EUS (Figure 27.11) has emerged as a very useful tool for visualizing the pancreas and peripancreatic structures by combining the advantages of endoscopy with ultrasonography. It can detect small tumours that are not visible on a CT scan and helps in assessing resectability of larger tumours by delineating their relationship to adjacent major vessels. It is however very dependent on the technical expertise and interpretation of an experienced individual. EUS, when available, has largely replaced diagnostic ERCP in the evaluation of the jaundiced patient. EUS-guided FNA of pancreatic masses and enlarged lymph nodes, and coeliac plexus nerve block are also being widely practised. EUS is used increasingly as the initial modality for evaluating pancreatic lesions. EUS alone is more sensitive (94%) than CT (69%) and MRI (83%) for detecting pancreatic lesions smaller than 3.0 cm. EUS has an accuracy of 93% in the prediction of local resectability compared with 60% for CT. The specificity of EUS is similar to angiography for the detection of vascular invasion.

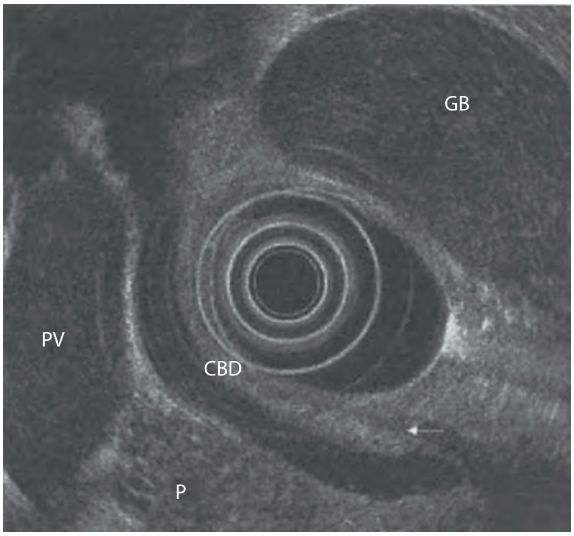

Figure 27.11 Endoscopic ultrasonography. CBD, common bile duct; GB, gallbladder; PV, portal vein; P, pancreas.

Ultrasound-guided FNA aspiration cytology is highly specific (99–100%) for the diagnosis of solid pancreatic lesions. The current diagnostic EUS-FNA criteria for pancreatic adenocarcinoma include increased cellularity; the predominance of one cell type; overlapping cells; multiple pleomorphic cells; tall cells with large nuclei (tombstones); and cells with increased nuclear/cytoplasmic and with coarse and clumped chromatin, macronucleoli and abnormal mitoses.

Increased cellularity is one of the important criteria in the differentiation of adenocarcinoma from chronic pancreatitis by EUS-FNA. However, the cellularity of a sample is influenced by several factors, including technique and the anatomic location of the lesion. Markedly cellular aspirates are obtained more frequently with EUS-FNA than with percutaneous FNA and for this reason the EUS-guided aspiration is preferred. Increased cellularity in FNA samples is also encountered in pancreatic islet cell tumours. Accurate diagnosis of an islet cell tumour and its differentiation from pancreatic adenocarcinoma, acinar cell carcinoma, and solid cystic pancreatic carcinoma is based on an assessment of morphological features and immunohistochemical staining.

Cytology alone is considered an insensitive test for the diagnosis of cystic pancreatic lesions; compared with solid pancreatic lesions, the overall sensitivity for FNA for establishing a definite diagnosis is reduced to 62% when applied to cystic pancreatic lesions. Nonetheless, EUS-FNA may be helpful but requires good technique for procurement and a very experienced pancreatic cytologist. Aspirates from microcystic adenomas yield hypocellular material containing cuboidal cells with bland nuclei and pale cytoplasm. Aspirates from mucinous cystic neoplasms are moderately cellular and demonstrate abundant mucinous material with glandular epithelial cells arranged in sheets and cohesive clusters. When present, the key cytological findings indicative of mucinous cystadenocarcinoma include moderate cellularity, loose clusters of cells, single cells, nucleoli, overt malignant nuclear features, and the presence of signet-ring cells. The features characteristic of intraduct papillary mucinous tumours (IPMTs) include large papillary groups with a fibrovascular core lying in pools of mucin. The neoplastic cells are columnar and show loss of cell polarity. The individual cells may demonstrate a wide range of morphological changes, from a preserved nuclear cytoplasmic (N/C) ratio and a regular nuclear membrane to marked anisocytosis, an increased N/C ratio and an irregular nuclear membrane with conspicuous nucleoli.

CEA, amylase, CA125 and CA19-9 from samples of the cyst contents have been used in the hope of increasing the sensitivity and specificity of the diagnosis. One recent study showed that non-invasive mucinous cystic neoplasms, irrespective of the degree of atypia, are positive for MUC5AC but negative for MUC1. In contrast, the lesions with an invasive component express MUC1. Thus the expression pattern of the MUC antigens may provide useful information for the determination of the invasive potential of a cystic mucinous lesion.

Pancreatic pseudocysts are distinguished from pancreatic cystic epithelial neoplasms by the predominance of histiocytes and inflammatory cells.

Magnetic resonance imaging

MRI makes use of the property of nuclear magnetic resonance to image nuclei of atoms inside the body. Modern MRI machines generate (1) powerful magnetic fields (1.5–3.0 T) to align the magnetized atoms of the body and (2) radiofrequency fields to alter the alignment of this magnetization. The response of the nuclei of the body tissues to this combined exposure is the production of a rotating magnetic field which is detected by the scanner and used to construct an image of the scanned region as strong magnetic field gradients cause nuclei at different locations to rotate at different speeds. Additionally, three-dimensional (3D) spatial imaging can be obtained by providing gradients in the x, y, z directions.

MRI provides good contrast between the different body tissues and is ideal for imaging the brain, muscles, heart and neoplasms. Its advantage over CT is that it does not expose the patient to ionizing radiation. There are various imaging techniques used in MRI but the most common are T_1 weighted and T_2 weighted imaging. T_1 weighted scans differentiate water (dark) from fat (bright) and use a gradient echo sequence with short echo time (T_E) and repetition (T_R). These techniques of MRI scanning can be used with or without a contrast agent (gadolinium) in which case T_1 scans are performed before and after administration of contrast. T_2 weighted MRI scans which use a gradient echo sequence T_E and long T_R are excellent for imaging fluid such as blood and bile etc. The special forms of MRI scanning include magnetic resonance angiography (MRA) based on the administration of paramagnetic contrast agents, magnetic resonance gated intracranial cerebrospinal fluid (CSF) dynamics (MR-GILD) used to investigated the CSF circulation in patients with obstructive lesions (e.g. hydrocephalus), functional MRI to study neural activity (mostly research) and MRCP. Increasingly MRI is also used for image-guided interventions and for guidance of tumour ablation by high-intensity focused ultrasound.

Technical advances, such as high field-strength (3.0 T) MRI with phased-array coils and ultrafast imaging have vastly improved the performance of MRI in the detection and staging of pancreatic cancer. MRI with a high gradient system and phased-array coils has a reported sensitivity of 95% for the diagnosis of pancreatic cancer, a positive predictive test of non-resectability 90% and a negative predictive test/verdict (tumour is operable) of 83%. MRI is also helpful in the detection or exclusion of pancreatic cancer in patients showing a prominent pancreatic head or uncinate process but no definite tumour on CT or ultrasound examination.

Magnetic resonance cholangiopancreatography

MRCP, which is based on T_2 weighted imaging, outlines the biliary tract with images which are similar to that obtained by ERCP by detection of the fluid contained in the biliopancreatic system (Figure 27.12).

Aside from its non-invasive nature, MRCP avoids the need for use of contrast and is therefore ideal for imaging of the entire biliopancreatic system in patients with known allergy to iodine-based contrast materials and in patients with a history of atopy. The diagnostic accuracy of MRCP is the same as that of ERCP for both benign and malignant disorders of the pancreas and biliary tract. However, ERCP has the advantage of permitting therapeutic interventions of the biliary and pancreatic ductal systems. In addition, ERCP enables inspection and biopsy of the periampullary region. 3D reconstruction from segmented MRI multislice imaging provides superb images of the biliopancreatic tracts.

Chemical analysis of the stool to demonstrate steatorrhoea

Stool examination for fat content is only useful as a screening test for malabsorption. Faecal fat excretion is not a valid measure of pancreatic dysfunction, since about 80% of pancreatic secretory capacity may be lost without any detectable change in the test. In clinical practice, pancreatic secretory deficiency states and malabsorption syndromes coexist in about 10–20% of patients. Even with more sophisticated tolerance tests, there is an overlap of the results obtained in malabsorption states and pancreatic insufficiency.

Direct measurement of pancreatic digestive and secretory capacity

Direct duodenal intubation and collection of pancreatic juice for analysis (duodenal drainage studies) following various stimuli is still widely practised largely as a research tool. The exact technique varies from institution to institution. In the Lund test, a meal of fat is given and the output of pancreatic lipase in the aspirated duodenal content is determined. The pancreatic secretory response to an injection of secretin (measurement of volume of juice and bicarbonate output) is often studied, but data interpretation is sometimes difficult. However, it is the most reliable test in detecting pancreatic exocrine insufficiency due to chronic pancreatitis or pancreatic carcinoma. Cytological examination of the duodenal aspirate during these maximal secretory tests sometimes documents the presence of malignancy in cases of pancreatic cancer.

Congenital anomalies of the pancreas

The pancreas may be totally absent but this condition is extremely rare and usually associated with other severe malformations that are incompatible with life. Pancreatic agenesis is associated with mutations of the *IPF1* gene on chromosome 13q12.1, which is a transcription factor essential for normal embryological development of the pancreas. The three congenital anomalies of the pancreas which are of surgical importance are ectopic pancreas, annular pancreas and pancreas divisum.

Ectopic (heterotopic, accessory, aberrant) pancreas

Ectopic pancreas (heterotopic, accessory or aberrant pancreas) is a rare developmental anomaly with varying estimates of 0.2–2% of the general population. It is defined as pancreatic tissue lacking anatomic and vascular continuity with the pancreas. These embryological rests are most commonly located in the distal stomach and duodenum followed by the jejunum, Meckel's diverticulum and less frequently the biliary tract, including the major duodenal papilla and other sites. Thus scattered pancreatic tissue has been reported in the gallbladder, colon, spleen, liver, bile ducts, mesentery and omentum. Some enterogenous cysts of the thorax have been reported to contain typical pancreatic tissue, including islets.

Ectopic pancreatic lesions are located most commonly in the submucosa (75%) and in the muscular layer or subserous coat in the remainder (Figure 27.13).

With the advent of widespread upper gastrointestinal endoscopy and improvements in contrast studies of the alimentary tract, ectopic pancreas of the stomach and duodenum is being more frequently recognized. The pathognomonic contrast radiological finding is a smooth, rounded filling defect with evidence of a tiny umbilication or even a small duct which may be outlined by a line of barium.

Ectopic pancreas is usually asymptomatic and discovered incidentally during endoscopy or laparotomy. However, it may become symptomatic because of the development of complications such as acute pancreatitis, pseudocyst, ulceration, gastrointestinal bleeding, gastric outlet obstruction, biliary obstruction with jaundice (ampullary lesions), intestinal obstruction and intussusception. In addition, there have been isolated reports of the development of malignant degeneration (pancreatic cancer) and islet tumours (duodenal insulinoma). When identified, the submucosal mass in the stomach or duodenum is initially misinterpreted as gastrointestinal stromal tumours as these account for 90% of gastric submucosal tumours or leiomyomas. There are no specific distinguishing features on CT scanning of lesions caused by ectopic pancreatic rests.

The symptoms are varied and include abdominal pain suggestive of ulcer dyspepsia, postprandial fullness and vomiting from gastric outlet obstruction, dyspepsia due to proven peptic ulceration, gastrointestinal bleeding and intestinal obstruction.

Annular pancreas

The exact embryological explanation for this malformation is debatable. The classic description of annular pancreas is almost

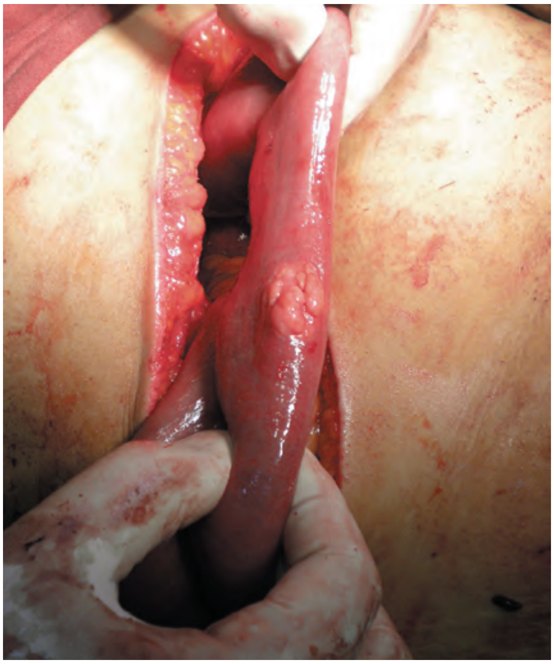

Figure 27.13 Ectopic serosal small bowel pancreas. (Courtesy of Professor Omar Shah, Srinagar, Kashmir, India.)

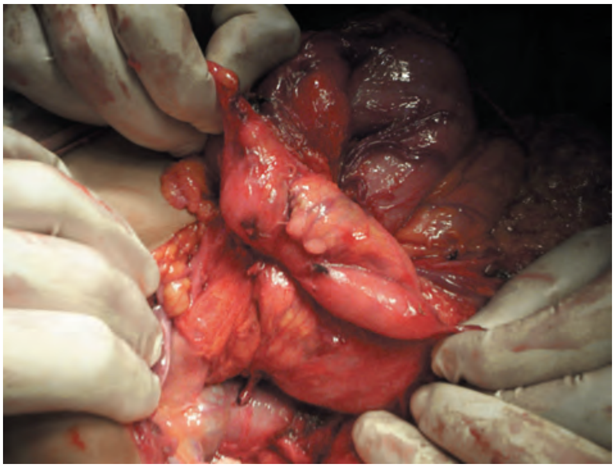

Figure 27.14 Complete annular pancreas. (Courtesy of Professor Omar Shah, Srinagar, Kashmir, India.)

invariably a ring of pancreatic tissue, continuous with the head of the pancreas, surrounding the second part of the duodenum proximal to the ampulla of Vater. However, the infra-ampullary location has also been documented. Eighty-five per cent of cases occur around the second portion of the duodenum, and the remaining 15% are scattered around the first or third part of the duodenum (Figure 27.14).

The pancreatic tissue is generally firmly attached to and embedded into the duodenal musculature; only rarely is it loosely attached and readily separable from the duodenum. There is usually a variable amount of hypertrophy of the proximal duodenal wall resulting from obstruction. Half of the reported cases have manifested themselves in the first year of life. Some believe that there is invariably an associated intrinsic atresia or stenosis of the duodenum. Other developmental anomalies are also present in about 60–70% of cases. They include Down syndrome, non-rotation and incomplete rotation of the mesentery, preduodenal portal vein, imperforate anus, oesophageal atresia with tracheoesophageal fistula and congenital heart disease. There is a high frequency of polyhydramnios in the mothers of those children who have significant duodenal obstruction at birth.

The exact incidence is unknown as many cases remain asymptomatic during life. However a postmortem study reported three cases in 20 000 autopsies. The condition is commoner in males. Vomiting is the main symptom of annular pancreas. It may begin as soon as the infant starts feeding or may appear several days later. Bile may or may not be present in the vomitus. Jaundice may be present and has been explained by back pressure of the distended duodenum on the common bile duct or involvement of the ampulla of Vater by oedema at the level of the stenosis. A plain film of the abdomen may show a distended stomach and a 'double-bubble' sign at the level of the duodenum. Contrast studies may be necessary to diagnose the condition.

About one-half of the cases reported present for the first time with symptoms between the ages of 21 and 70 years. The reason for such late manifestations of symptoms is generally attributed to inflammatory changes in the pancreatic ring. Duodenal ulcer, frequently reported with annular pancreas in the adult, has not been reported in infancy. The differential diagnosis in infancy rests between annular pancreas and other causes of duodenal obstruction, all of which require urgent operative relief, namely duodenal stenosis or atresia, compression of the duodenum by Ladd's bands, pyloric stenosis or volvulus in association with malrotation. An absolute differentiation between annular pancreas and duodenal atresia or stenosis is not possible without operation.

The operation of choice is either duodenoduodenostomy or duodenojejunostomy performed through the retrocolic route. Attempts at division of the pancreatic ring are attended with complications, including pancreatitis, pancreatic fistula, duodenal wall perforation and failures. Gastrojejunostomy is not a satisfactory operation since it inadequately decompresses the duodenum and has a high incidence of marginal ulceration. In patients with concomitant jaundice, an operative cholangiogram is mandatory before a decision about the need for and type of biliary diversion which can be made. Pancreas divisum and its implications are discussed in the section on pancreatitis.

Injuries to the pancreas

Pancreatic injuries occur infrequently in patients with abdominal trauma of all types and this may be accounted for by the relatively protected position of the gland in the retroperitoneum beneath the thoracic cage. Pancreatic trauma is often classified according to the source of the injury: (1) penetrating trauma; (2) blunt trauma; and (3) iatrogenic trauma. Although the pancreatic injury rarely, if ever, accounts for the early death of a patient, it adds significantly to the morbidity and late mortality, especially if it is recognized late.

Injuries to the pancreas are being encountered more frequently nowadays. This is attributed to the increasing incidence of motor vehicle accidents and civil violence. There is also some evidence that the compulsory use of seat belts in Western countries may have contributed to the increase in the incidence of blunt pancreatic trauma, since the gland may be ruptured by sudden compression against the lumbar spine. The overall mortality rate from pancreatic trauma is about 20%. Stab wounds have a mortality rate of about 8%, gunshot wounds 25% and shotgun wounds 60%. The mortality following blunt trauma from steering wheel injury is still approximately 50%. One-third of all pancreatic injuries are secondary to blunt trauma and two-thirds are due to penetrating trauma in the USA. The majority of early deaths result from massive haemorrhage and shock, from the associated injuries to major vascular structures.

Diagnosis

In less than 10% of patients with pancreatic trauma of all types is the pancreas found to be the only injured organ. This implies that over 90% of patients will have further internal injuries. In the clinical situation, patients with definite evidence of an injured intra-abdominal viscus and/or intra-abdominal haemorrhage following blunt or penetrating trauma to the abdomen are in need of an emergency laparotomy following adequate resuscitation. They should not be investigated further. The initial emphasis is placed on adequate resuscitation rather than an elaborate, time-consuming and often unrewarding investigation. The diagnosis and the extent of the injury is made intraoperatively.

On the other hand, patients with doubtful evidence of intra-abdominal injury after blunt trauma who are haemodynamically stable should be observed and carefully investigated as dictated by clinical circumstances. There are a small group of patients in whom an isolated pancreatic injury may easily be missed.

Classification of pancreatic injuries

Pancreatic injuries can be classified as follows:

- simple contusion
- parenchymatous laceration without major ductal injury
- major ductal disruption
- combined pancreatoduodenal injury.

Penetrating pancreatic trauma

Isolated pancreatic injury is very rare. Associated injuries include liver, stomach, major vascular structures, spleen, duodenum, colon and kidney. Early death is invariably due to the associated injuries which can lead to catastrophic, often uncontrollable, haemorrhage. Late death accounts for some 41% of all mortality and is attributable to the pancreatic injury, leading to intra-abdominal abscess, sepsis and multiorgan system failure.

The emphasis in the management of penetrating injuries of the abdomen is on resuscitation with minimal essential investigations. The diagnosis is made at laparotomy. A long midline laparotomy is performed to provide good access and exposure. Management of associated injuries takes precedence over any pancreatic injury. The underlying principles are (1) arrest haemorrhage, (2) control contamination from the gastrointestinal tract and (3) once the patient is stabilized, the lesser sac is widely opened and all peripancreatic haematomas are explored. If there is no major ductal disruption, selective pancreatic and peripancreatic debridement is performed only as necessary. Adequate external drainage is instituted and, if the patient develops a pancreatic fistula, it can be treated conservatively with a combination of total parenteral nutrition and somatostatin analogue.

Blunt pancreatic trauma

About 50% of patients with blunt pancreatic trauma will have an isolated pancreatic injury. If the patient is stable and the diagnosis of significant injury is doubtful, then the patient is observed and is investigated rationally. The only test that is of definite diagnostic value is CT with intravenous and oral contrast. Occasionally, a flat X-ray plate of the abdomen, EUS, ERCP and abdominal angiography may be useful. Serum amylase and lipase elevation or lack thereof are not usually helpful in this clinical situation, although if these enzymes are highly elevated, they will strengthen a diagnostic suspicion of pancreatic injury. If the patient is unstable and there is evidence of an injured abdominal viscus, the patient should be rapidly resuscitated and explored as for a penetrating pancreatic injury.

Treatment of major pancreatic ductal disruption

If the injury is well to the left of the mesenteric vessels, the simplest manoeuvre is to perform a distal pancreatectomy and splenectomy with oversewing of the cut end of the proximal pancreas. In children under 16 years of age, one may elect empirically, if conditions are favourable, to attempt preserving the spleen with its blood supply based on the short gastric vessels.

If the injury is close to or to the right of the superior mesenteric vessels, pancreatic preservation may be considered. The preservation of pancreatic tissue is often desirable, but should not become an irrational obsession. A partial pancreatic transection may be completed and the area debrided as necessary. The right side of the transection may be oversewn as before and the cut end of the left pancreas may be implanted into a Roux-en-Y loop of jejunum.

The decision to preserve pancreatic tissue and perform a pancreatoenteric anastomosis is based on (1) the magnitude of the associated injuries, (2) the general condition of the patient, (3) the degree of contamination and (4) the surgeon's expertise and experience in pancreatic surgery.

Pancreatoduodenal injuries

The duodenal injury has to be repaired on its own merits. Following duodenorrhaphy, the injury to the pancreatic head has to be evaluated. Minor lacerations with or without ductal injury can be appropriately debrided and drained. If the ductal injury and the trauma to the head parenchyma appear extensive, a duodenal diversion procedure can be performed. An incision is made in the distal antrum and the pylorus is closed with a running catgut suture. A distal gastrojejunostomy is performed using the antral incision to 'protect' the duodenal repair (Figures 27.15 and 27.16).

For more extensive trauma, the duodenal diverticulization procedure of Berne is sometimes advocated. This entails a distal gastrectomy, Billroth II gastrojejunostomy, T-tube insertion for drainage of the common bile duct, and duodenostomy tube drainage (Figure 27.17).

In all these extensive injuries, a duodenal and/or pancreatic fistula will eventually develop and this can be treated conservatively with total parenteral nutrition and a long-acting somatostatin analogue. If the fistula does not spontaneously close after a few months, then a secondary attempt to drain it into an isolated bowel loop can be considered.

Occasionally, especially with gunshot wounds to the right upper abdomen, extensive devitalization of the duodenum and pancreatic head is seen with avulsion of the common bile duct and uncontrollable haemorrhage. In such a situation, the surgeon may have no choice but to 'complete' the pancreatoduodenectomy if only to control haemorrhage, usually from the superior mesenteric vessels, the renal vessels and the inferior vena cava. It is not unusual in such situations to be forced to perform a concomitant right nephrectomy. An experienced surgical team is needed for this type of injury since the mortality is in excess of 30%.

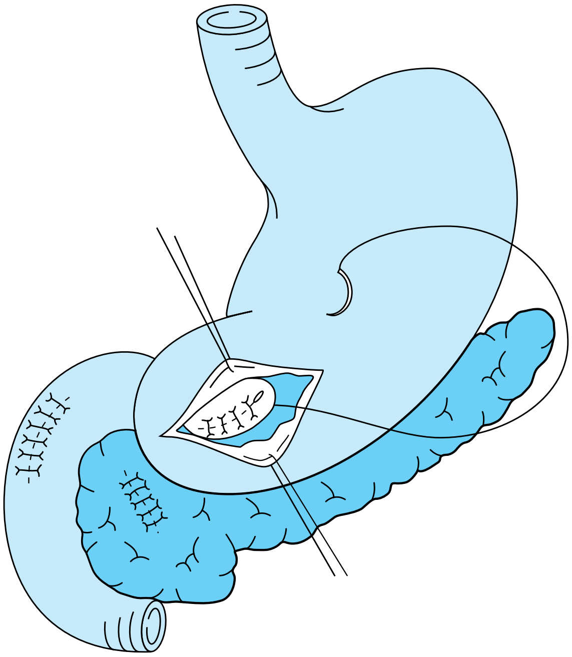

Figure 27.15 Pyloric exclusion procedure. The pylorus is oversewn through an antral incision.

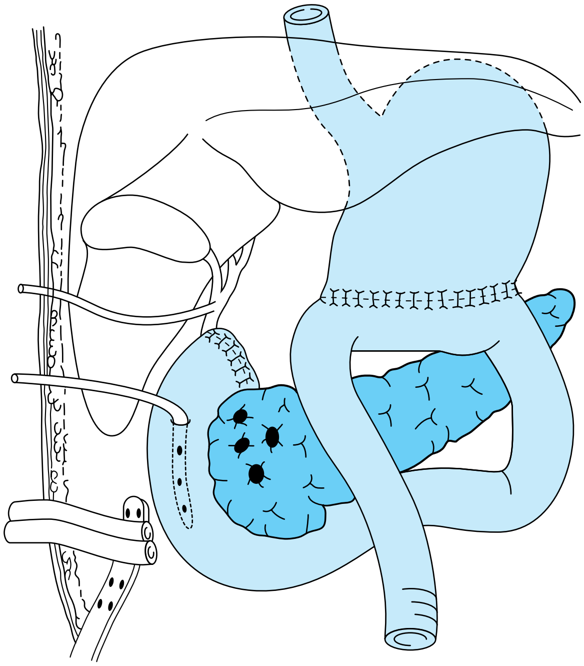

Figure 27.17 Duodenal diverticulization for major pancreatoduodenal injuries.

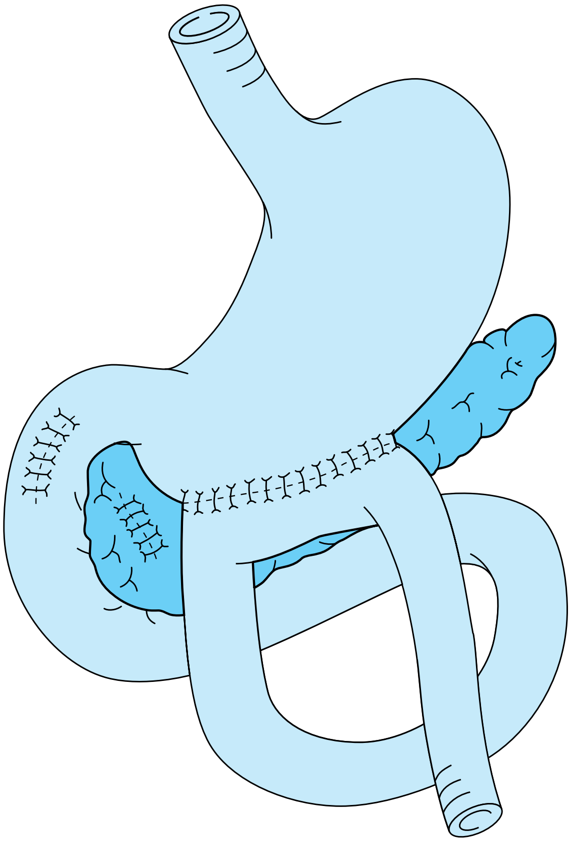

Figure 27.16 Pyloric exclusion procedure. A gastrojejunostomy is constructed through the previous antral incision.

Iatrogenic pancreatic trauma

The commonest cause of iatrogenic pancreatic trauma is ERCP with or without associated sphincterotomy and stent placement. Multiple pancreatic biopsies are another cause, whether performed percutaneously or intraoperatively. Occasionally, surgical operations on a large penetrating duodenal ulcer may also lead to severe pancreatic injury. Other surgical procedures which may lead to inadvertent pancreatic trauma are splenectomy, inexpert exploration of the common bile duct and transduodenal sphincteroplasty. All these invasive manoeuvres may lead to a fulminant pancreatitis with serious sequelae.

Pancreatitis

Definition and classification

The term ‘pancreatitis’ implies the presence of pancreatic inflammation and autodigestion. It can be classified according to its clinical presentation, according to the aetiological factors or according to the severity of the pathological process. Clinically, pancreatitis is referred to as acute or chronic. *Restitutio ad integrum* is the hallmark of the acute form, whereas persistence or progression of the disease or residual damage to the pancreas indicates the chronic variety. Nevertheless, if a patient recovers from acute necrotizing pancreatitis, normal recovery of pancreatic (endocrine and exocrine) function or morphology may never occur and the patient may be rightly labelled as having ‘progressed’ into chronic pancreatitis. Similarly, on occasion, recurrent attacks of acute pancreatitis due to any cause may merge into the chronic varieties. The emphasis on chronic pancreatitis is the absence of enzyme elevation and pancreatic exocrine and endocrine insufficiency. Patients with chronic relapsing pancreatitis, in addition to the same disorders of function, experience pain which, in the overt case, is constant with acute exacerbations against the background of pain. All types of acute or chronic pancreatitis may cause complications such as biliary tract obstruction, splenic vein thrombosis and duodenal obstruction.

Acute pancreatitis

Although, experimentally, acute pancreatitis has been produced in various animal models by promoting duodenopancreatic reflux, by the injection of bile salts, trypsin, etc., into the pancreatic duct, or by the occlusion of pancreatic arterial blood supply, the relevance of these models to the human clinical situation remains uncertain. Acute pancreatitis has been associated with a variety of clinical disorders, but the actual cause or mechanism which initiates the pancreatic autodigestion or which makes it either a self-limiting disease or a progressively fatal disease remains unclear. Acute pancreatitis developing in the course of viral infection, such as mumps and coxsackie B viruses, is usually self-limiting. So is the acute pancreatitis in association with mycoplasma pneumonia. Metabolic disorders, such as hypercalcaemia (usually associated with contraceptive pills), have been well documented. So has acute pancreatitis resulting from drug therapy, such as diuretics and steroids. Autopsy examinations of patients dying of such conditions as fulminant liver failure, hypovolaemic shock with renal tubular necrosis, transplantation and cardiac bypass surgery have revealed fulminant pancreatitis in a significant number of these patients. From the practical point of view, the two conditions most commonly associated with acute pancreatitis are alcoholism and biliary tract stone disease. The prognostic and therapeutic implications of acute pancreatitis due to these two associations are different. Gallstone pancreatitis usually occurs in patients older than 60 years, tends to be severe and is frequently accompanied by serious complications in the acute stage. However, recurrences may be prevented by early operative intervention or, if the patient recovers quickly, by appropriately timed elective surgical treatment of the biliary tract. By contrast, alcohol-associated pancreatitis tends to be recurring. Although the first attacks are usually quite severe, and can be fatal, subsequent attacks are commonly mild and carry low mortality. As time passes, the recurring attacks lead to progressive destruction of the gland and eventually the clinical picture merges into that of chronic pancreatitis or chronic relapsing pancreatitis.

Acute pancreatitis may be secondary to blunt or penetrating abdominal injury or may follow some invasive clinical test, such as ERCP and the now rarely performed translumbar aortography. Postoperative acute pancreatitis most commonly occurs after exploration of the common bile duct and is invariably due to injudicious, inexpert, forceful dilatation of the sphincter of Oddi or transduodenal sphincteroplasty. Distal pancreatitis may follow splenectomy.

Disease severity

The original Atlanta classification defined mild (oedematous) and severe categories of acute pancreatitis but is no longer appropriate in view of the improved understanding of the pathophysiology of acute pancreatitis and the importance of systemic complications on outcome and survival. It is now recognized that the severity of acute pancreatitis depends on several factors: (1) the number of organs that fail, (2) their onset and response to initial treatment and (3) the development of systemic (infectious) complications. Organ failure lasting for >48 hours is associated with increased mortality. The revised Atlanta classification includes all such patients as having severe disease as distinct from patients with transient organ failure who are considered to have mild/moderate acute pancreatitis. Local (peripancreatic) complications are not included in the category of severe acute pancreatitis unless accompanied by infection which is responsible for the high morbidity and mortality rather than the peripancreatic complications *per se*, as demonstrated by a retrospective study from the Mayo Clinic, which reported that patients with local pancreatic complications but without systemic complications had a negligible mortality (2%) despite an appreciable morbidity requiring a significant stay in intensive care and prolonged total hospital stay of 28 days. This study has been confirmed by a subsequent prospective study from the same institution and a prospective study from Spain. Thus, the revised Atlanta classification proposed by Petrov and Windsor includes a third category of moderate acute pancreatitis to include patients with local (peripancreatic) complications but no persistent systemic complications (previously graded as having severe acute pancreatitis). The Petrov–Windsor revised Atlanta classification recognizes a fourth category, which includes patients with both local peripancreatic and systemic complications (organ failure) during the course of acute pancreatitis. This category of extremely severe or critical acute pancreatitis identifies patients at high risk of mortality from the illness (28–58%) in various reports.

The classification and definitions of the four categories of the severity of acute pancreatitis are shown in Table 27.1.

Clinical features

The clinical manifestations of acute pancreatitis are protean since it can mimic any other abdominal emergency. In fact, it can coexist with some such as acute cholecystitis. It can occur at any age, but is rare in children and in very young adults. In the latter group, it is usually associated with infections,

Table 27.1 The classification and definitions of the four categories of the severity of acute pancreatitis

Severity category	Local complications		Systemic complications
Mild	No peripancreatic complications	and	No organ failure
Moderate*	Sterile peripancreatic complication	or	Transient organ failure
Severe*	Infectious peripancreatic complication	or	Persistent organ failure
Critical	Infectious peripancreatic complication	and	Persistent organ failure

*Severity is graded on the basis of more severe local or systemic complication (e.g. sterile pancreatic necrosis without organ failure has to be graded as 'moderate'; sterile pancreatic necrosis with persistent organ failure has to be graded as 'severe').

trauma, parasites or drugs or may be hereditary. Alcohol-related pancreatitis is usually found in the young adult less than 40 years of age, whereas the form associated with biliary tract disease manifests itself mainly in middle-aged and older persons.

The onset of symptoms may follow excess intake of food or alcohol but this is not invariable. Pain is the major initial symptom in over 90% of patients. It may vary in degree from mild to severe and is characteristically sudden in onset persisting for 12–48 hours or more. The wide spectrum of the intensity of the pain should be emphasized. Like many patients with pancreatic pain, there is a tendency for the patient to bend forward and assume various postures in order to obtain relief. Occasionally, even severe disease may be totally painless. The location of the pain is usually in the mid-epigastrium but can occur or radiate anywhere and may be diffuse or confined mainly to the back. Other common symptoms are nausea, vomiting, retching and hiccups. Less frequently, diarrhoea, dyspnoea, cyanosis, haematemesis and melaena may appear early. The bleeding may be due to erosive ulcers, bleeding diathesis, left-sided portal hypertension or erosion of the inflammatory process into the gut.

The physical findings may be minimal, in striking contrast to the severity of the symptoms. Obtundation, fever, tachycardia, epigastric tenderness and muscle guarding are frequent. Shock may be the initial symptom and in critical acute pancreatitis may be profound. Mild jaundice may be observed. Abdominal distension is often present in the early phase of the disease and is the result of a diffuse or localized paralytic ileus. Several days later, a palpable epigastric mass may be felt, indicating the development of peripancreatic complications, e.g. pseudocyst or marked peripancreatic fat necrosis. Other late signs (rarely encountered) include bluish discoloration of the skin around the periumbilical area (Cullen's sign) or in the loins (Grey Turner's sign); these indicate ecchymosis caused by seepage of blood arising from acute necrotizing pancreatitis along fascial planes. Another rare skin manifestation is nodular fat necrosis simulating erythema nodosum or Weber–Christian disease. Rarely, polyarthritis or bone pain may be observed and is also attributable to fat necrosis. Thrombophlebitis of the leg veins is only rarely seen. Abnormal physical findings on chest examination are found in less than one-third of cases, but a plain chest radiograph may reveal abnormalities in a greater proportion of patients. These include elevation of the diaphragm, basal atelectasis or pneumonitis, left-sided or bilateral pleural effusion.

Diagnostic procedures

The haematocrit is high in most patients at the onset of the disease, reflecting fluid loss related to the inflammatory process and vomiting. Leucocytosis with a white blood count of $10–20 \times 10^9$/dL is almost invariably present.

Serum enzyme elevations

The key to the diagnosis of acute pancreatitis remains an elevation of pancreatic enzymes in the circulating blood or urine. Although hyperamylasaemia is a non-specific finding, the level of the serum amylase in various extrapancreatic conditions rarely attains a value five times above normal and this is commonly seen in primary acute pancreatitis. Normal serum amylase levels may be obtained if the determination is carried out 3 days or more after the onset, if previous attacks have completely destroyed the glandular tissue or if the current attack is associated with massive destruction of the gland. Persistence of hyperamylasaemia for 10 days or longer may indicate a continuation of the acute inflammation or the development of local peripancreatic complications and may be accompanied by pancreatic ascites.

In view of the problems involved in the interpretation of hyperamylasaemia, measurement of isoenzymes of amylase and determinations of the renal amylase creatinine clearance ratio are used. The P-type isoamylase cannot be detected after extirpation of the pancreas and hence is only of pancreatic origin. Its measurement is unnecessary and time consuming for routine purposes but it is useful in establishing the cause of a persistent hyperamylasaemia. In acute pancreatitis, the relative renal clearance of amylase increases compared with that of creatinine. It has been suggested that a clearance of amylase over the clearance of creatinine of greater than four is found in the first few days after an attack of acute pancreatitis and that this elevated ratio persists longer than abnormalities of blood or urinary enzyme levels. The view that the amylase–creatinine clearance is specific for acute pancreatitis has now been shown to be untrue since an elevated clearance ratio is found in many other conditions, such as diabetic ketoacidosis, burns and chronic renal failure, whereas many patients with acute pancreatitis may have normal clearance ratios.

Estimation of lipolytic activity in the blood, urine, pleural and peritoneal effusions has been advocated on the grounds that lipase is more specific for pancreatic disease than amylase and its level remains elevated for longer periods. The recent introduction of radioimmunoassay for trypsin has resulted in reports demonstrating high levels of immunoreactive trypsin in the circulation and in serous effusions, in patients with acute pancreatitis. The diagnostic or prognostic value of immunoreactive trypsin assays compared with other enzymes has yet to be confirmed. Immunoreactive elastase levels have also been reported and are said to be elevated in patients with acute pancreatitis showing good correlation with levels of amylase.

Urinary amylase and lipase

Amylase clearance is increased about threefold for 1–2 weeks in patients with acute pancreatitis whose renal function is unimpaired. Thus, increased urinary output of amylase may persist for several days after normalization of the serum amylase levels. Determination of the ratio of amylase–creatinine clearance permits the diagnosis of acute pancreatitis even in the presence of renal insufficiency. Timed urinary amylase output (usually expressed in terms of total activity per hour) and amylase clearance studies are particularly of diagnostic value after serum amylase has returned to normal. Urinary lipase determination has been abandoned since it is debatable whether lipolytic activity is detectable in the urine.

Hyperglycaemia and glycosuria

Transient hyperglycaemia has been observed in a varying proportion of patients with acute pancreatitis. One of the mechanisms may be the release of glucagon from the damaged pancreatic cells. Usually the hyperglycaemia disappears with remission of the acute pancreatitis but, occasionally, following extensive parenchymal damage, diabetes mellitus may ensue.

Hypocalcaemia

The incidence, mechanism and prognostic implications of hypocalcaemia (serum calcium below 1.9 mmol/L or 7.5 mg/100 mL) are still controversial. Some believe that hypoalbuminaemia accounts for most of the measured hypocalcaemia. Deposition of calcium in areas of fat necrosis, release of glucagon with secondary hypercalcitonaemia and hypomagnesaemia have all been suggested as pathogenetic factors. Impairment of parathyroid gland function has also been reported. Whatever its mechanism, hypocalcaemia complicating acute pancreatitis is occasionally manifested by tetany and usually denotes the presence of the severe form of the disease.

Methaemalbuminaemia

The presence of this haemoglobin derivative in the serum suggests severe haemorrhagic pancreatitis. Elevated methaemalbumin levels, however, are not specific for necrotizing pancreatitis, because they can occur with other necrotizing intra-abdominal processes.

Blood coagulation tests

A rise in circulating trypsin may result in an increased antithrombin activity, but this is not a reliable test for acute pancreatitis. The persistence of elevated serum fibrinogen levels, especially after the second week, is said to indicate either a severe form of acute pancreatitis or the onset of complications.

Hyperlipidaemia

Hyperlipidaemia, especially hypertriglyceridaemia, occurs in about 5–10% of patients with acute pancreatitis. The lipid rise may be primary and/or the cause of the acute pancreatitis or it may be secondary to the pancreatitis. Long-term studies of blood lipids after subsidence of acute pancreatitis may be necessary for the differentiation of primary and secondary hyperlipidaemia. It has been suggested that many of the patients with so-called ‘secondary hyperlipidaemia’ may have a primary disorder of lipid metabolism which is unmasked by the attack of pancreatitis.

Electrocardiogram

Electrocardiogram (ECG) changes simulating myocardial infarction have been reported in patients with acute pancreatitis. The commonest ECG changes are S–T segment elevation or depression, inversion of T-waves, and extended T-wave negativity. These changes disappear rather quickly unless there is coexistent myocardial ischaemia or infarction or there are other cardiac complications of acute pancreatitis, such as pericarditis. The exact mechanisms underlying the ECG changes include several factors, such as myocardial damage due to shock, electrolyte disturbance, excessive parenteral fluid replacement, effect of severe pain on coronary artery disease, influence of circulating pancreatic trypsin, and vagally mediated reflexes from the pancreas to the heart.

Plain abdominal and chest radiography

A plain radiograph of the abdomen and chest may show evidence of pneumoperitoneum, thus excluding the diagnosis of acute pancreatitis and indicating the need for emergency operation for a perforated viscus. It may show abnormalities suggestive of acute pancreatitis in about 50% of cases. The radiological signs include intestinal distension in the region of the pancreas (sentinel jejunal loop, colon cut-off, duodenal ileus) or a generalized paralytic ileus. Haziness in the flat plate of the abdomen is caused by retroperitoneal fluid accumulation and may be associated with obliteration of the psoas outline. Other signs are elevation of the left diaphragm caused by basal atelectasis or subdiaphragmatic fluid collection, and pleural effusions.

Imaging techniques used in patients with acute pancreatitis

Contrast-enhanced CT is the standard imaging technique for detection of acute pancreatitis. It has 78% sensitivity and 86% specificity for severe acute pancreatitis. CT generally is not indicated for patients with mild uncomplicated disease but is reserved for patients with severe disease or worsening of the clinical and biochemical profile. Costs aside, the potential risk of contrast medium morbidity is the reason for limiting its use only to severe or deteriorating disease.

ERCP is helpful in evaluating less common causes of pancreatitis, e.g. microlithiasis, sphincter of Oddi dysfunction, pancreas divisum, etc. Urgent ERCP is indicated in patients at risk or with evidence of (1) biliary sepsis, (2) severe pancreatitis with biliary obstruction, (3) cholangitis, (4) rising bilirubin with worsening/persistent jaundice and (5) worsening pain in patients with an abnormal ultrasound examination. These patients need urgent biliary decompression. Several clinical trials have confirmed that, in patients with severe gallstone pancreatitis, morbidity and mortality are reduced with early interventional ERCP (papillotomy, stenting, etc.).

Although MRI is not commonly used, it is certainly indicated when improved visualization of peripancreatic inflammation, necrosis or fluid collections is needed.

MRCP is used preoperatively to determine which patients would benefit from ERCP as it has high (81–100%) sensitivity for detecting ductal calculi. Moreover, recent data indicate it to be as accurate as contrast-enhanced CT in predicting the severity of pancreatitis and identifying pancreatic necrosis (83% sensitivity and 91% specificity) in severe disease. EUS is useful in obese patients and in patients with ileus. It can determine which patients would benefit from interventional ERCP and can assist with endoscopic transmural cyst and abscess drainage.

Differential diagnosis

The clinical picture of acute pancreatitis tends to change with evolution of the disease. Early (2–3 hours) after the onset, symptoms are often suggestive of acute cholecystitis and, indeed, acute cholecystitis may coexist with acute pancreatitis. After 6–8 hours a perforated duodenal ulcer or acute appendicitis may be simulated. After 2–3 days, the clinical features may mimic those of an intestinal obstruction because there is marked abdominal distension and ileus. If the patient presents with profound cardiovascular collapse, myocardial infarction, acute aortic distension, ruptured aortic aneurysm, mesenteric infarction or even massive pulmonary embolism may be initially suspected. Most of these conditions may be associated with elevation of serum amylase and often of lipase. Improved diagnostic ability will result if the clinical limitations in assessment are fully appreciated. Thus, the diagnosis of acute pancreatitis is based on 'thinking about it as a possibility' and excluding other sources of abdominal pain.

Predictors of severity of acute pancreatitis

It is important to identify patients with severe to critical acute pancreatitis early (day 1 or 2 of admission) because timely administration of broad-spectrum, pancreas-penetrating antibiotics decreases the incidence of pancreatic and peripancreatic infection. Two well-controlled studies have shown a convincing benefit of imipenem when administered within 48 hours of onset and maintained for 10 days to 2 weeks in patients with severe pancreatitis. The incidence of pancreatic/peripancreatic infection is halved, from 40% to 20%. Predictors of severity fall into three main categories: clinical (long-established), biochemical and radiological (based on CT).

Clinical scoring systems

The sensitivity of clinical judgement, even in experienced hands, is low (about 40%) for predicting the severity of an acute attack of pancreatitis. Because of the subjective nature of the clinical acumen, Ranson developed 11 objective criteria and postulated that the risk of death and/or developing major complications may be estimated objectively by five parameters on admission to hospital and six parameters within the initial 48 hours of admission.

The clinical predictors of severity of acute pancreatitis according to Ranson are shown in Table 27.2.

Table 27.2 Clinical predictors of the severity of acute pancreatitis, according to Ranson

	Ranson criteria	
	Non-biliary	**Biliary**
Admission		
Age (years)	>55	>70
WBC	>16 000	>18 000
Glucose	>200	>220
LDH*	>350	>400
AST*	>250	>250
First 48 hours		
↓Hct	>10	>10
↑Urea	>5	>2
Ca^{2+}	<8	<8
PaO_2	<60	<60
Base deficit	>4	>5
Fluid requirement	>6	>4

*International units/mL.
AST, aspartate transaminase; Hct, haematocrit; LDH, lactate dehydrogenase WBC, white blood cell count.

In patients with fewer than three of these 11 prognostic factors the mortality rate is low (0.9%), with three or four factors, 18%; with five or six factors, 50%; and with more than six factors, 90%.

Imrie proposed the Glasgow (Imrie) criteria which are based on eight of Ranson's factors. The presence of any three of the eight signs at anytime within 48 hours of admission indicates a severe form of the disease (Table 27.3).

While these combined criteria are better than clinical judgement at predicting the severity and prognosis of acute pancreatitis, they pose some limitations: (1) they require data from the initial presentation and 48 hours to mature; (2) evaluation of the patient after 48 hours may be problematic; and (3) the criteria are not pancreas specific. They measure the systemic response to an inflammatory process in and around the pancreas and do not predict specific complications, e.g. severe necrosis, infection, pseudocyst and organ failure.

Of the clinical grading systems, the APACHE II system is currently the best and easiest scoring system available to assess the severity of acute pancreatitis and can be used *at any time* in the course of the disease. It is more sensitive and specific than the Ranson or Imrie criteria and is the clinical scoring system of choice. The APACHE II system allocates three sets of points: A, B and C. The A points assess clinical parameters, e.g. vital signs, electrolytes and arterial blood gases. The B points are allocated according to chronological age. The C points take into consideration comorbidity or chronic health of the patient. The APACHE II score is the sum of the A, B and C points. If it exceeds 9, the patient has severe acute pancreatitis. If the score increases after admission, the mortality is extremely high (Table 27.4).

Biochemical markers

Several biochemical 'markers' of the severity of acute pancreatitis have been studied (Box 27.1).

Ideally, any serum or urinary marker must be pancreas specific, originating from the organ producing the marker. Serum amylase or lipase is of *no* value. Thus far, four pancreas-specific markers appear promising in discriminating between mild and severe pancreatitis: (1) trypsin-activated peptide is a five amino acid peptide released by activation of trypsinogen and can be measured in the urine; early reports indicate a sensitivity of 80% and specificity of 90%; (2) phospholipase A_2 tends *not* to decrease in severe acute pancreatitis but the methodology of the assay has

BOX 27.1 Biochemical markers of severity of acute pancreatitis

Pancreas specific

- Trypsin-activated peptide
- Phospholipase A_2
- Pancreatitis-associated protein
- Trypsinogen-2
- Ribonuclease
- Elastase 1
- Antichymotrypsin
- Carboxylic ester hydrolase
- Procarboxypeptidase β

Non-pancreas specific

- C-reactive peptide
- Procalcitonin

PMN elastase

- α_1-Antitrypsin
- α_2-Macroglobulin
- Methaemalbumin

been questioned and its value is uncertain; (3) the pancreatitis-associated protein is a protein purified from the pancreatic juice of rats with experimental pancreatitis – the human counterpart correlates well with the severity of pancreatitis, but the changes in concentration take days to a week to become established; (4) procalcitonin, which appears to be an early marker of severe disease; (5) serum trypsinogen-2, which is reported to be 91% sensitive and 71% specific as an index of severe disease, but further confirmation is needed. At present, none of these pancreas-specific markers can be considered to be of value in routine clinical practice.

The most extensively studied non-specific marker of acute pancreatitis is the C-reactive protein (CRP). This acute phase protein can reliably differentiate mild from severe acute pancreatitis but it is only useful after the second to third day of the disease. Its sensitivity is high (about 95%) but its specificity is low (about 50%). CRP concentration in excess of 100 mg/dL usually indicates necrotizing pancreatitis. However, its clinical value is diminished because it requires a few days to help in the identification of severe disease.

Another approach to staging acute pancreatitis is to monitor interleukins (ILs) or complement activation as a monitor of the local and systemic inflammatory response (Box 27.2). Tumour necrosis factor, IL-2, IL-6 and IL-8 have been extensively studied in experimental pancreatitis. Clinically, IL-6 and IL-8 seem to be as useful as CRP levels and peak about 1 day earlier. However, their value in routine clinical practice is as yet uncertain. Clinical studies with complement activation factors C3 and C4 have thus far been disappointing.

Radiological assessment: CT Severity Index

This is the sum of the CT grade of the condition of the pancreas (0–4) and the necrosis score (0–6).

- CT grade
  - A is normal pancreas = 0
  - B is oedematous pancreas = 1
  - C is B plus mild extrapancreatic changes = 2
  - D is severe extrapancreatic changes plus one fluid collection = 3
  - E is multiple or extensive fluid collections = 4
- Necrosis score
  - None = 0
  - >One-third = 2
  - <One-third but less than one-half = 4
  - >One-half = 6

Some studies have indicated superiority of the CT Severity Index in predicting the severity of acute pancreatitis compared with the other clinical systems (Ranson's criteria and APACHE II). A CT Severity Index score of 5 or greater correlates with prolonged hospitalization and higher mortality and morbidity rates. However caution is necessary with the interpretation of these comparative studies as, in most cases, the CT Severity Index was conducted 72 hours after admission, whereas the APACHE II scale and Ranson's criteria scores were calculated earlier – at 24 and 48 hours, respectively, although one study in which the CT Severity Index scores were obtained within 48 hours of admission reported similar findings. Thus the CT Severity Index is undoubtedly useful if available, but is unlikely to replace

BOX 27.2 Interleukins as indicators of the local and systemic inflammatory response to acute pancreatitis

- Tumour necrosis factor
- Interleukin 2
- Interleukin 6*
- Interleukin 8*
- Serum complement factor C3
- Serum complement factor C4

*Markers of macrophage activation.

clinical scoring systems in the short term, especially APACHE II, which demands constant monitoring of the patient, an integral component of medical treatment. Scoring systems apart, signs of organ failure within 24 hours of admission is a bad prognostic sign as it is invariably associated with increased mortality.

Treatment of acute pancreatitis

Medical management

The treatment of acute pancreatitis is essentially medical (conservative) in the first instance and is based on the following principles:

- volume replacement as required
- control of pain
- close monitoring of haemodynamic status, organ failure and development of peripancreatic complications
- maintenance of nutritional state
- active intervention (surgical, endoscopic, radiological) for infective complications.

There is now good evidence that total enteral nutrition is superior to parenteral nutrition in these patients, although some debate still exists on the type of total enteral nutrition (oral, nasogastric or nasojejunal) that is most effective in improving patient outcome. Nonetheless randomized studies have confirmed that enteral feeding reduces morbidity and mortality, possibly by prevention of bacterial translocation from the gut and thus infection of any necrosis. However, enteral nutrition cannot be used in patients with paralytic possible, when nutritional status is maintained by parenteral feeding. The issue of prophylactic antibiotic therapy initiated on admission remains debatable. One recent randomized trial (ciprofloxacin, metronidazole) against placebo reported no significant difference in the incidence of infected pancreatic necrosis (IPN), systemic complications and mortality. This is in disagreement with earlier trials and a recent systemic review which reached the opposite conclusion – prophylactic antibiotic therapy reduces infectious complications (pancreatic and extrapancreatic) and mortality. As prophylactic antibiotic has its risks (promotion of fungal infections and drug resistance), the decision on its use is difficult in view of the existing conflicting data. Selective use in patients with severe disease or bad prognostic criteria would seem to be a reasonable compromise.

The mainstay of the medical treatment of acute pancreatitis entails correction of hypovolaemia by replacement of fluid, electrolytes, blood or plasma. The continuing activity of the pancreatitis and/or the development of complications may be assessed by serial clinical examination, monitoring of serum and/or urinary amylase, and by regular CT scan of the pancreas. Current evidence suggests that anticholinergics, glucagon or Trasylol, and octreotide have no place in the management of patients with acute pancreatitis.

Medical management also includes close monitoring of vital signs, hourly urine output and central venous pressure measurements. Arterial blood gases must be frequently measured during the first few days as clinically occult respiratory failure is common. Pulmonary arterial pressure monitoring is valuable in patients with large volume requirements and especially in those with associated cardiopulmonary disease or respiratory failure. Such careful and repeated evaluation will also permit accurate differentiation between acute pancreatitis and other acute illnesses in the majority of cases. Selected patients may also need additional investigations, such as contrast studies of the alimentary tract, isotope biliary scanning to exclude with absolute certainty gastrointestinal perforation or obstruction, acute biliary tract disease, or mesenteric infarction.

Surgical management

Early surgical intervention

There are three situations when early operative intervention is indicated in a patient with suspected acute pancreatitis.

- When the diagnosis is in doubt and a perforated or a gangrenous viscus cannot be excluded.
- Patients with known biliary stone disease who develop an attack of acute pancreatitis which does not improve within 48–72 hours, especially if there is evidence of biliary obstruction and/or cholangitis. In this clinical setting, one must suspect an impacted stone at the ampulla and emergency ERCP with endoscopic papillotomy and stone extraction is indicated. If this fails or if an experienced endoscopist is not available, then early operation to relieve ampullary obstruction is mandatory.
- The patient who recovers following conservative management of acute gallstone pancreatitis has a high risk of recurrence. Early operative treatment of the cholelithiasis should be undertaken as soon as the pancreatitis has subsided, preferably during the same hospitalization.

It should be stressed that early abdominal exploration with pancreatic drainage or necrosectomy has an increased mortality in patients with severe pancreatitis. Peritoneal lavage by catheters placed percutaneously, coupled with adequate resuscitation, is effective in the management of early cardiovascular, respiratory and renal complications of severe pancreatitis, reducing early deaths from those causes. However, improvement in overall mortality following peritoneal lavage has been disappointing since lavage does not reduce the late deaths from pancreatic and peripancreatic necrosis and sepsis. It should be emphasized that peritoneal lavage and laparotomy are emergency resuscitative measures for the patient who is in refractory cardiovascular collapse and respiratory embarrassment. They should not be used indiscriminately for all cases of acute pancreatitis. If laparotomy is performed, the addition of a gastrostomy and jejunostomy confers several advantages. The former always allows gastric decompression and drainage which may be needed for several weeks without the discomfort of a nasogastric tube. The latter provides a route for enteral nutrition and obviates the use of intravenous alimentation which has the potential risk of catheter sepsis. It was rightly pointed out that the two surgical pitfalls in acute pancreatitis are (1) to operate too early and do too much and (2) to operate too late and do too little.

Any patient who has persistence or reappearance of inflammatory manifestations of acute pancreatitis must be suspected of developing a pancreatic pseudocyst or a pancreatic abscess. Clinically, fever, pain, tenderness, a palpable mass, leucocytosis and hyperamylasaemia are inconstant features. A positive blood culture is not usually obtained in the early development of a pancreatic abscess. If antibiotics are used, the fever may be partly masked. A plain radiograph of the abdomen may demonstrate the mottled 'soap bubble' appearance suggestive of a retroperitoneal abscess in less than 20% of cases. CT is an invaluable tool in these cases and obviates the need for contrast studies of the gastrointestinal tract.

Apart from the eradication of biliary tract disease following an attack of acute pancreatitis which has subsided, the role of operative intervention late in the course of acute pancreatitis is for the treatment of complications:

- IPN/abscess formation
- pseudocyst formation
- haemorrhage resulting from pseudoaneurysms or sectorial (left-sided) portal hypertension.

Management of pancreatic pseudocyst

A pancreatic pseudocyst is a collection of fluid in the lesser sac and its walls have no recognizable epithelial lining. However, at some point, most pseudocysts connect with the pancreatic glandular tissue or ductal system and the discharge of fluid into the cyst is maintained via the connection. Microscopic examination of this area of a pseudocyst will reveal some epithelial lining. The majority of pancreatic epithelial cysts are neoplastic (Table 27.5)

The differentiation between a true cyst and a pseudocyst is only possible by histology. However, the epithelial lining of true cysts may atrophy due to overdistension or infection. Hence, the absence of histologically recognizable epithelium in the cyst wall on biopsy may be of no significance. Two types of pancreatic pseudocysts can be differentiated. Acute pseudocysts (acute peripancreatic effusions) follow an established acute attack of pancreatitis. They should be managed expectantly for 4–6 weeks. Spontaneous resolution often occurs and surgical therapy is more satisfactory if the cyst wall is allowed to mature. *Chronic pseudocysts* are usually asymptomatic and, often, no recent attacks of acute pancreatitis can be identified. Spontaneous resolution is rare and delay only invites the high risk of complications. The commonest cause of pancreatic pseudocysts in children is blunt abdominal trauma. Pancreatic pseudocyst is a common complication of chronic pancreatitis occurring in 20–40% of cases.

Table 27.5 Cysts of the pancreas

True cysts	Pseudocysts
Benign cysts	
Enterogenous cyst	(1) Acute pseudocyst following acute pancreatitis
Retention (solitary) cyst	(2) Chronic pseudocyst following acute pancreatitis
Dermoid cyst	(3) Chronic pseudocyst associated with chronic pancreatitis
Lymphoepithelial cyst	(4) Miscellaneous peripancreatic cysts
Cystic fibrosis	– hydatid cyst
von Hippel–Lindau disease	– choledochal cyst
Endometrial cyst	– postpancreatitis necrotic collections
Neoplastic cysts	
Serous cystadenoma	
Mucinous cystadenoma	
Cystadenocarcinoma	
Papillary cystic neoplasm	
Solid malignancies with central necrosis and cavitation	

The other parameters which are helpful in the management of pancreatic pseudocysts are listed below.

- Size – pseudocysts less than 5 cm in diameter may be observed and expected to resolve in many instances. Those greater than 7.5 cm in diameter will probably need surgical drainage.
- The development of symptoms is indicative of an impending complication such as rupture, haemorrhage and infection.
- Maturity – acute pseudocysts should be allowed to mature for 4–6 weeks to allow the cyst wall to mature since this facilitates internal drainage.
- Vascular complications – visceral angiography delineates a subgroup of patients with vascular complications associated with acute pancreatitis. These include pseudoaneurysms and left-sided portal hypertension from splenic vein thrombosis. If arterial complications are suspected, an arteriogram is helpful especially if preoperative arterial embolization is contemplated. The presence of portal hypertension is an indication for splenectomy.
- The site of the pseudocyst is another important parameter which helps the surgeon decide on the method of internal drainage. Retrogastric cysts which are enlarging anteriorly are best treated by a posterior cystogastrostomy. Cysts around the head of the pancreas close to the duodenum can easily be drained by cystoduodenostomy. Large cysts which enlarge through and bulge inferiorly into the transverse mesocolon are best drained by cystojejunostomy with Roux-en-Y. Cysts located in the tail or body of the pancreas are technically more amenable to a resection (distal pancreatectomy and splenectomy) than cysts in the head and neck of the gland.

Although internal drainage into the upper gastrointestinal tract is the preferred method of treating pseudocysts, there are some exceptions. Infected or ruptured cysts or the acute cysts with thin, friable walls are best drained externally with wide-bore sump suction drains. In many instances, the resulting pancreatic fistula will gradually close spontaneously. Occasionally a second procedure is needed to implant the fistulous tract into the Roux-en-Y loop of jejunum. Two additional precautionary measures should be taken whenever a pancreatic cyst is drained:

1. The cyst fluid must be routinely sent for cytological examination and a representative sample of the cyst wall must be excised for histological examination. The injudicious drainage of a cystadenoma or a cystadenocarcinoma may thus be spotted and a planned reoperation for wide local excision entertained.
2. The cavity of the cyst must be explored with the index finger and septa gently divided. The cyst must be thoroughly irrigated prior to anastomosis with adjoining bowel or external drainage.

Percutaneous drainage of a pseudocyst under CT scan or ultrasound guidance is often advocated indiscriminately. It definitely has a temporizing role in some specific situations such as:

- a patient who is unfit for or who refuses an operation
- an acute pseudocyst which is rapidly enlarging and needs external drainage

- an infected pseudocyst which needs external drainage in a very sick septic patient
- a pseudocyst which is in an unusual location (e.g. mediastinum, pelvis) and is not readily amenable to internal drainage.

Alternative treatments for pancreatic pseudocysts

Although open surgical treatment remains the gold standard in the management of pancreatic pseudocysts, alterative techniques are used depending on the clinical state of the patient, the pathological anatomy of the pseudocysts and the available expertise. The alternative approaches include radiological (usually CT) percutaneous drainage which remains unpopular, endoscopic drainage which may be supplemented by EUS guidance and laparoscopic drainage.

Endoscopic drainage of pancreatic pseudocysts

Endoscopic drainage can be performed through the major papilla (transpapillary) or through the gastric (endoscopic cystogastrostomy) or duodenal walls (endoscopic cystoduodenostomy). The procedure may be performed with or without EUS guidance. Certain considerations determine the suitability of a particular patient for endoscopic cyst drainage. These include:

- site of cyst apposition to the gastric or duodenal wall
- determination of a site suitable for enterostomy
- presence of communication between the cyst and pancreatic duct or biliary duct
- cyst fluid consistency – solid material in the pseudocyst (detected by EUS) may preclude complete drainage and is an indication for surgery (open or laparoscopic)
- exclusion of malignancy.

Transpapillary drainage

Transpapillary drainage is successful only when the cyst is in communication with the pancreatic ductal system. Overall this is encountered in 60% and is more common with pseudocysts complicating chronic pancreatitis. Following documentation of the anatomy by the pancreatogram obtained during ERCP, a guide wire is passed through the pancreatic sphincter into the pseudocyst and pancreatic sphincterotomy performed. A stent is then passed over the guide wire preferably into the pseudocyst or to the site of ductal communication if the pseudocyst cannot be entered. A nasocystic drain can also be placed for additional drainage. A potential serious complication of transpapillary drainage is infection with abscess formation. Thus preprocedure antibiotics are used as prophylaxis together with preventive measures aimed at ensuring stent patency until the cyst drainage is achieved. EUS is advisable before transpapillary drainage to exclude solid debris from liquefied necrosis as this constitutes an absolute contraindication in view of the high infection rate in such cases. Transpapillary drainage has a success rate of 85%, with an average recurrence of 15% and morbidity of 8–12% (acute pancreatitis, infection).

Transenteric drainage without EUS guidance

This includes cystogastrostomy and cystoduodenostomy. Endoscopic cystoduodenostomy is nowadays preferred because of its increased safety, improved drainage and the relative dependency of the duodenum compared with the stomach for most pseudocysts. A luminal bulge by the cyst is required. In its absence, needle localization may require multiple passes with increased risk of complications. Thus it is important that the stomach or the duodenum share a common wall with the pseudocyst. CT scanning may be used for this, but EUS provides better confirmation of the contiguity of the wall between the cyst and the stomach or duodenum. Successful drainage is achieved in 90% with virtually no mortality. Complications of transenteric drainage include haemorrhage (6%), postprocedural pancreatitis, retroperitoneal perforation (3%) and infection or recurrence (6%) due to difficulty in maintaining an adequate fistula. There is virtually no mortality associated with the procedure.

EUS-guided endoscopic drainage

EUS provides important advantages in endoscopic drainage of pseudocysts, including accurate measurement of the distance between the enteric wall and the pseudocyst wall (distance >1 cm is considered a contraindication), detection of gastric varices associated with pancreatitis (contraindicates the procedure), imaging of gastric vessels with identification of pseudoaneurysms and detection of debris within pseudocysts which precludes effective drainage and increases the risk of infection. Nonetheless its superiority over the standard non-EUS-guided transenteric drainage remains to be confirmed by future studies.

Laparoscopic treatment of pancreatic pseudocysts

Laparoscopic treatment of pancreatic pseudocysts provides equivalent results to those of open surgery with the addition of the important clinical advantages in terms of accelerated postoperative recovery and reduced hospital stay. There are two techniques: laparoscopic infracolic cystenterostomy (Figure 27.18a–c) or transgastric stapled cystogastrostomy (Figure 27.18d, e). The transgastric cystogastrostomy is greatly facilitated by the hand-assisted laparoscopic surgery approach.

In a systemic review based on 19 laparoscopic and 25 endoscopic publications on the results of patients who underwent 118 and 583 laparoscopic and endoscopic drainage procedures, respectively, the pancreatic pseudocysts were considerably larger in the laparoscopic series (mean 13 vs 7 cm). Despite this, successful resolution of the pseudocyst was higher in the laparoscopic series (98%) than in the endoscopic series (81%), with morbidity rates of 4% and 12% and mortality rates of 0% and 0.4%, respectively. In the follow-up period, which was however significantly shorter in the laparoscopic series (mean 13 vs 24 months), the recurrence rates were 2.5% in the laparoscopic series and 14.4% for the patients treated endoscopically. The reintervention rate was also lower in the laparoscopic series (1% vs 12%). Obviously longer follow-up studies are needed to confirm the superiority of the laparoscopic approach.

Management of pancreatic abscess/infected pancreatic/peripancreatic necrosis

The term 'pancreatic abscess' should not be used to connote a localized collection of pus in the lesser sac (infected pancreatic

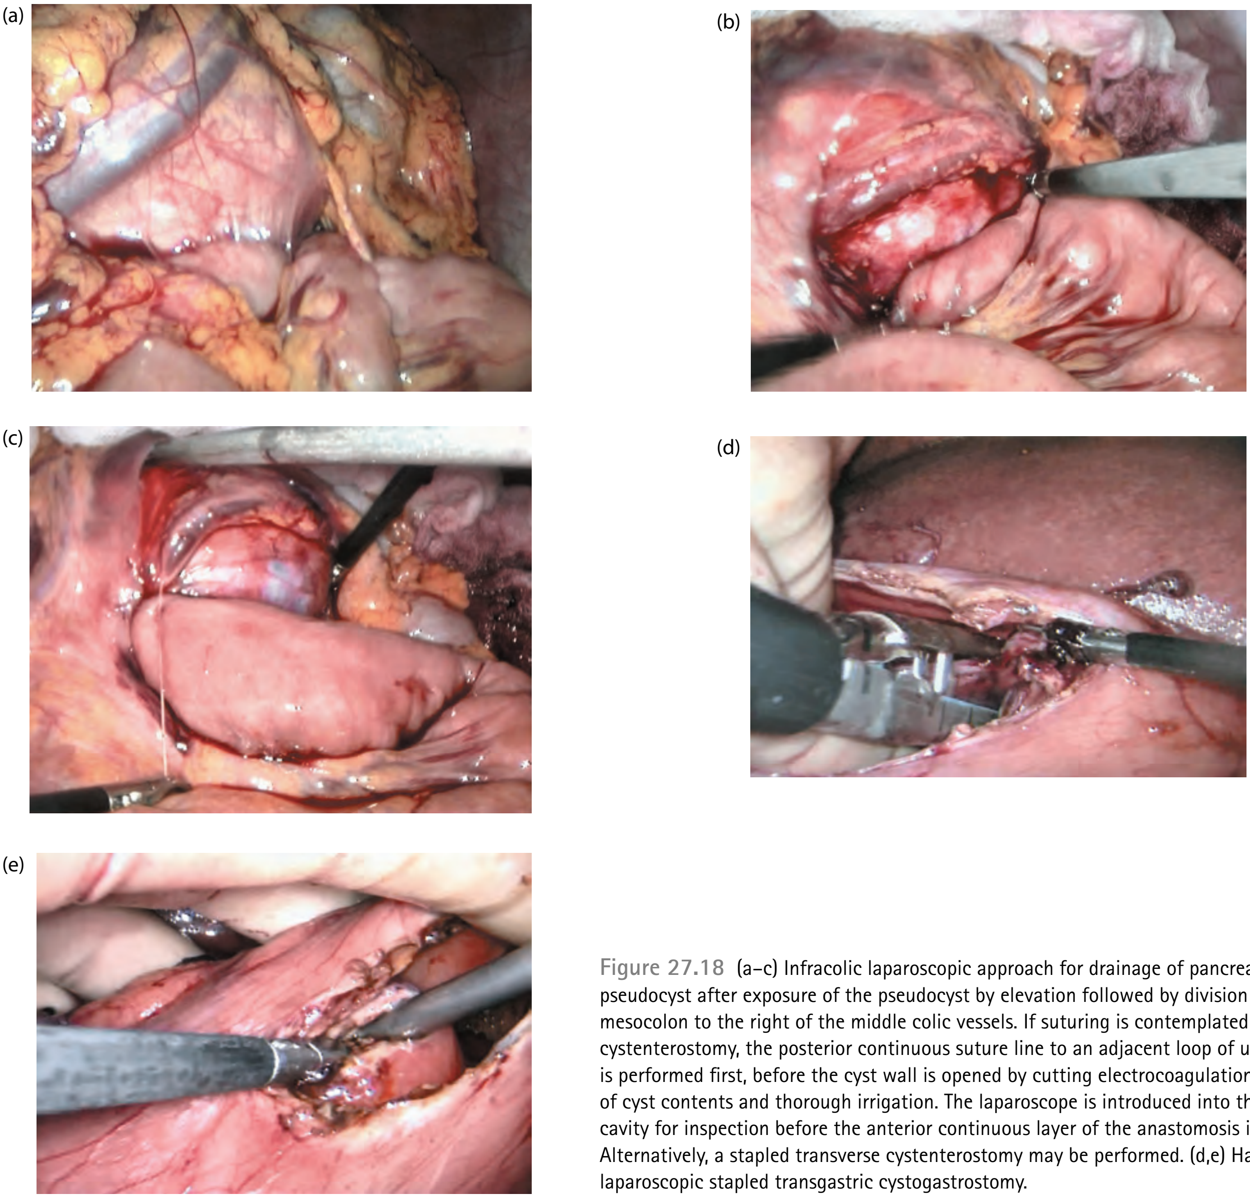

Figure 27.18 (a–c) Infracolic laparoscopic approach for drainage of pancreatic pseudocyst after exposure of the pseudocyst by elevation followed by division of the mesocolon to the right of the middle colic vessels. If suturing is contemplated for the cystenterostomy, the posterior continuous suture line to an adjacent loop of upper jejunum is performed first, before the cyst wall is opened by cutting electrocoagulation, aspiration of cyst contents and thorough irrigation. The laparoscope is introduced into the cyst cavity for inspection before the anterior continuous layer of the anastomosis is completed. Alternatively, a stapled transverse cystenterostomy may be performed. (d,e) Hand-assisted laparoscopic stapled transgastric cystogastrostomy.

pseudocyst) which is easily drained externally with good results. A pancreatic abscess implies the presence of extensive pancreatic and peripancreatic necrosis with secondary infection. Nowadays the term IPN (infected pancreatic necrosis) is used to avoid confusion. IPN carries a very high mortality and morbidity and usually occurs after the second week of the onset of pancreatitis. IPN is always accompanied by organ failure and other systemic complications and may be further complicated by massive haemorrhage.

Infection of the pancreatic necrosis is thought to arise by translocation of enteric bacteria probably from the transverse colon. The most commonly isolated bacteria in IPN are *Escherichia coli, Klebsiella pneumoniae, Enterococcus faecalis, Staphylococcus aureus, Pseudomonas aeruginosa, Proteus mirabilis* and *Streptococcus* species, and the infection is often mixed. It is important to stress that non-IPN diagnosed by CT is not an indication for surgery and necrosectomy unless the condition of the patient is deteriorating. Evidence-based guidelines for the management of IPN include:

- CT-guided or ultrasound-guided FNA for bacteriology should be performed in patients suspected of having IPN
- IPN accompanied by signs of sepsis is an indication for surgical intervention
- patients with sterile pancreatic necrosis should be managed conservatively, and surgical intervention only performed in selected cases, e.g. those with persistent organ failure or severe clinical deterioration despite maximum intensive care
- early surgical intervention (before third or fourth week) for IPN is not usually indicated as delay enables softening and demarcation
- necrosectomy with drainage is recommended as the surgical treatment for IPN
- drainage after necrosectomy is essential
- percutaneous drainage may be performed for pancreatic abscess but if this fails to improve the clinical condition, immediate surgical drainage is necessary.

The role of appropriate prophylactic antibiotic therapy remains controversial but has gained support in clinical practice.

The choice of antibiotics is based on the expected microbial flora and the extent of antibiotic penetration into the abscess/necrotic tissue. Although case series have been reported of patients treated successfully without surgical intervention but with CT-guided drainage, this is not the orthodox recommended treatment, although it is indicated in patients who cannot tolerate an open procedure. Thus surgery is the mainstay of treatment for IPN but several unresolved issues remain, including selection of patients for surgery, optimal timing for the intervention and the technique. The absence of infection is not an absolute contraindication, as although the vast majority of these patients can be successfully treated without surgical intervention there is a small subset of patients (10%) in whom extensive necrosis warrants surgery because of deteriorating organ failure despite maximal support or persisting symptoms which preclude hospital discharge despite several weeks of conservative treatment.

The timing of surgery is an important determinant of outcome. Early surgery (within the first week) is avoided in view of the reported high mortality. Surgery for IPN should be undertaken in the 3–4 weeks after onset when demarcation and softening of the necrosis has taken place, thus minimizing the risk of bleeding during the necrosectomy. The aim of operation is to remove the necrotic tissue and to provide adequate drainage for the remaining debris while preserving viable pancreatic tissue.

The standard recommended approach is by open laparotomy, although other alternative less invasive approaches are currently being evaluated in specialist centres:

- laparoscopic infracolic transmesocolic necrosectomy with closed peritoneal drainage and irrigation (Buerger's irrigation)
- laparoscopic transgastric necrosectomy with external drainage
- retroperitoneal necrosectomy and drainage with endoscopic (video-assisted) or radiological guidance.

To date, the reported experience with these minimal access techniques has been limited to a few centres and, although the reported results have been very promising in terms of reduced mortality in these critically ill patients, selection of cases is important and, for the time being, the general consensus is that these minimal access approaches should be confined to specialist centres. The experience in Dundee, UK, with the laparoscopic infracolic necrosectomy and closed peritoneal drainage and irrigation (Figure 27.19) has been positive in reducing mortality though it has not reduced the hospital stay of the surviving patients.

Thus delayed open surgery remains the gold standard treatment for IPN, although the technique is not standardized and different centres use one of the following:

- necrosectomy combined with open packing
- planned staged relaparotomies with repeated lavage
- necrosectomy with closed continuous lavage of the retroperitoneum (Beger's technique)
- necrosectomy with closed packing.

The reported series however indicate that necrosectomy with closed continuous lavage of the retroperitoneum or closed packing seem to be associated with a lower morbidity.

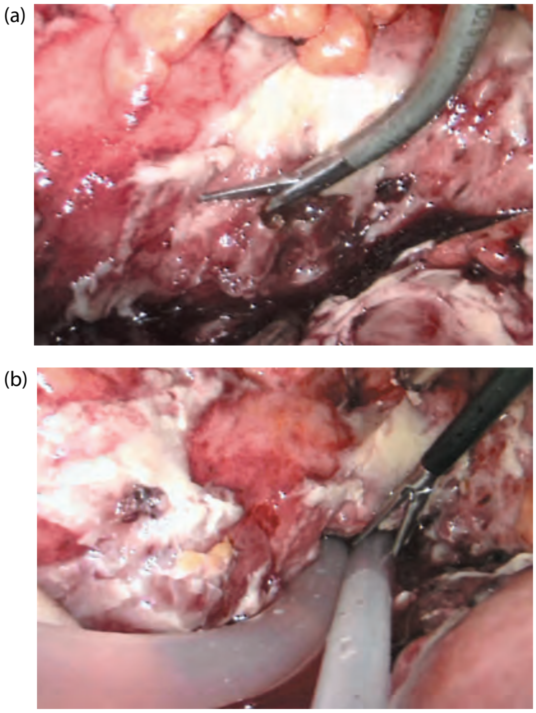

Figure 27.19 (a,b) The infected pancreatic necrosis is approached infracolically after elevation of the transverse colon and division of the transverse mesocolon to the right of the middle colic vessels. Only a small hole (enough to admit a 5 mm suction device) is made and the infected liquid contents aspirated before pulsed irrigation and extension of the opening for the necrosectomy which is stopped as soon as oozing of blood is detected. Two large drains are inserted for postoperative irrigation and drainage with hypertonic dialysate solution.

Recurrent pancreatitis

Any patient who has recovered from one or more attacks of pancreatitis must be investigated to identify and, if possible, to eliminate the aetiological factors. The need to identify surgically remediable problems, most commonly gallstones, is obvious. Ultrasonography of the biliary tract can be used even in the acute stage.

Stenosis of the sphincter of Oddi, often called papillitis, is without doubt a rare cause of recurrent pancreatitis. The stenosis is rarely of a primary nature and is probably due to a temporary impaction and later passage of a gallstone. Confidence in the diagnosis is strengthened by:

- documented episodes of biliary obstruction or cholangitis
- the endoscopic visualization of an inflamed papilla
- demonstrated tightness of the ampullary orifice when it is cannulated endoscopically
- documentation of delay in emptying of the common bile duct
- intermittent elevations of liver enzymes, especially serum alkaline phosphatase
- positive morphine–prostigmine (Nardi) test – reproduction of pain and enzyme elevation
- documentation of elevated pressures in the common bile duct by ERCP.

Treatment is sphincteroplasty, which includes division of the sphincter of Oddi and the septum between the common bile duct and the pancreatic duct to relieve both biliary and pancreatic outflow obstruction. The situation should be suspected in patients who have had more than one attack of pancreatitis and/or cholangitis without any other discernible cause. One word of caution – the condition of 'primary papillitis' has been overdiagnosed without adequate documentation of unexplained abdominal pain which is often not even of pancreatic or biliary origin. In such situations, the indiscriminate use of sphincteroplasty, often wrongly performed, has led the operation into disrepute. Endoscopic papillotomy has a definite place when the biliary sphincter alone needs to be divided.

Congenital malformations in the pancreas or duodenum around the ampullary region can cause recurrent pancreatitis in both children and adults. EUS and ERCP are invaluable in delineating these abnormalities, some of which may be amenable to surgical correction. Probably the commonest congenital abnormality leading to recurrent pancreatitis is the pancreas divisum, which is an anatomical variant occurring when there is failure of the two embryonic pancreatic ductal systems to unite. In this situation, the duct of Wirsung is very small and may measure no more than 1–2 cm in length while the duct of Santorini becomes the major ductal drainage system of the pancreas and maintains its communication with the duodenum through the minor papilla. Following secretin administration, large volumes of juice can be visualized endoscopically from the minor papilla with little or none coming from the main papilla or aspirated from the duct of Wirsung during cannulation. The high incidence of recurrent pancreatic pain in patients with pancreas divisum may well be due to the very small papilla of the duct of Santorini which, in these patients, drains the majority of the pancreas, creating a marked relative stenosis of the ampulla.

The relief of pain by all treatment modalities is unsatisfactory leading one to question the proposed pathophysiological explanation. Endoscopic papillotomy, with or without stenting of the duct of Santorini, and surgical transduodenal sphincteroplasty of both the minor and major papilla have not yielded favourable long-term results. Eventually, the recurrent pancreatitis coupled with the trauma induced by repeated endoscopic and/or surgical approaches force the surgeon to consider a Whipple pancreatoduodenectomy or a duodenum-preserving proximal pancreatectomy for pain relief.

Left-sided (sectorial) portal hypertension due to pancreatitis

This occurs from occlusion by compression or by thrombosis of the splenic vein and is discussed elsewhere (Chapters 24 and 26).

Acute pancreatitis in children

In recent years, acute pancreatitis is being recognized with greater frequency in infancy and childhood. Although the treatment is not substantially different from that of adults, the aetiological factors are totally different. Biliary tract disease is not usually an aetiological factor; nor is alcoholism. A large number of mild acute pancreatitis results from viral infections such as mumps. Blunt abdominal trauma, resulting from relatively minimal injury, is probably the most common cause. Unlike the situation in adults, isolated pancreatic injury is commonly reported. A trifling fall upon a toy, such as a tricycle handlebar, may result in pancreatic trauma sufficient to induce a traumatic pancreatitis. Two clinical pictures emerge: (1) an acute abdominal emergency necessitating exploratory laparotomy when the pancreas is found to be inflamed – in such situations, care must be taken to exclude a complete pancreatic transection or major ductal injury; (2) the initial symptoms are mild and often the child is not even taken to the hospital for several days or weeks when a pancreatic pseudocyst or pancreatic ascites has developed.

Drug-induced pancreatitis, familial pancreatitis (usually associated with hyperlipidaemia or amino aciduria) and calculous disease of the biliary tree are all uncommon in children, although occasional cases with pigment stones due to congenital spherocytosis have been described. Obstruction of the ampulla of Vater due to a congenital anomaly of the pancreatic ductal ampulla has also been documented and has been corrected by an adequate sphincteroplasty. Roundworms entering into the pancreatic duct and causing pancreatitis have also been reported from time to time. Duodenal obstruction due to an annular pancreas may lead to current acute pancreatitis which responds to duodenal decompression.

The management of acute or recurrent acute pancreatitis in children is essentially the same as in adults. The prognosis is much better even in the presence of complications. If the aetiological factors are removed, recovery is complete. Acute or recurrent acute pancreatitis does not progress into the chronic or chronic relapsing form in the vast majority of children.

Chronic pancreatitis

Chronic pancreatitis is defined as a continuing inflammatory disorder of the pancreas characterized by irreversible pathological changes which cause abdominal pain and/or permanent impairment of pancreatic exocrine and endocrine function. The disease may present clinically with an individual symptom or a combination of symptoms but by far the commonest presentation is with pain, which may be either intermittent or chronic and persistent, leading to regular narcotic opiate intake and addiction. The natural history of chronic pancreatitis is characterized by progressive damage of the pancreatic parenchyma with various degrees of exocrine and endocrine pancreatic insufficiency becoming clinically manifest with time: malabsorption and diabetes mellitus. The progressive fibrosis may also lead to large bile duct obstruction and deepening jaundice. Chronic pancreatitis increases significantly the risk for the development of pancreatic cancer, and in jaundiced patients with established disease, differentiation between chronic pancreatitis and ductal adenocarcinoma of the pancreas may be extremely difficult despite intensive investigations including pancreatic biopsy. Not infrequently, the exact pathology in the individual patient can only be established after pathological examination of the resected specimen following a pancreaticoduodenectomy.

Classification

Despite considerable research, there is as yet no internationally agreed classification of chronic pancreatitis that unifies the clinical features, the varied aetiology and radiological appearance. Some such as the Marseille classification and its various updates over the years distinguish the morphological, functional and clinical features of three types: (1) acute relapsing pancreatitis, (2) chronic pancreatitis and (3) chronic relapsing pancreatitis. The Cambridge classification recognizes two types as distinct forms of the disease: (1) chronic calcifying pancreatitis and (2) chronic inflammatory pancreatititis.

Perhaps the most useful is the TIGAR-O, which classifies chronic pancreatitis on aetiology (**T**oxic and metabolic, **I**diopathic, **G**enetic, **A**utoimmune and **R**ecurrent and severe acute pancreatitis, associated chronic pancreatitis, and **O**bstructive). The TIGAR-O classification has certain merits: (1) it includes a group of patients with genetic disorders which predispose to chronic pancreatitis induced by various agents, and (2) it considers the subset of patients with severe acute pancreatitis with severe parenchymal damage leading to chronic disease. Even so, this classification fails the clinical surgeon in staging the severity of the disease and indicating the morphological type (dilated duct as distinct from small duct disease) which in the end dictates the type of surgical intervention, if and when this becomes indicated.

The various categories of the TIGAR-O classification (version 1.0) are listed below.

1. Toxic–metabolic: alcoholic, tobacco smoking, hypercalcaemia, hyperparathyroidism, hyperlipidaemia, chronic renal failure, medications (phenacetin abuse), toxins (organotin compounds, e.g. DBTC).
2. Idiopathic: early onset, late onset, tropical, tropical calcific pancreatitis, fibrocalculous pancreatic diabetes.
3. Genetic: autosomal dominant – cationic trypsinogen (codon 29 and 122 mutations); autosomal recessive/modifier genes – *CFTR* mutations, *SPINK1* mutations; cationic trypsinogen (codon 16, 22, 23 mutations), α_1-antitrypsin deficiency.
4. Autoimmune: isolated autoimmune chronic pancreatitis (AIP), syndromic AIP, Sjögren syndrome-associated chronic pancreatitis, inflammatory bowel disease-associated chronic pancreatitis, primary biliary cirrhosis-associated chronic pancreatitis.
5. Recurrent and severe acute pancreatitis: postnecrotic (severe acute pancreatitis) recurrent acute pancreatitis, vascular diseases/ischaemic, postirradiation.
6. Obstructive: pancreatic divisum, sphincter of Oddi disorders, duct obstruction (e.g. tumour), preampullary duodenal wall cysts, post-traumatic pancreatic duct scars

Especially in Western countries, alcohol abuse is by far the most common cause of chronic pancreatitis, although only 10–20% of chronic alcoholics develop acute or chronic pancreatitis. This observation indicates the interaction of genetic or other environmental cofactors in the pathogenesis of alcoholic pancreatitis, and, indeed, an increased prevalence of genetic mutations known to produce chronic pancreatitis has been documented in some of these patients. Smoking is associated with increased risk for chronic pancreatitis which is independent of alcohol use. The constituents of tobacco smoke decrease pancreatic secretion, induce oxidative stress and increase the development of pancreatic calcification. Drug-induced pancreatitis is much more usually acute rather than chronic pancreatitis.

The important metabolic conditions associated with acute and chronic pancreatitis are (1) hypercalcaemia and (2) chronic renal failure. Severe hypercalcaemia can cause acute pancreatitis through trypsin-mediated mechanisms. Persistent untreated hypercalcaemia will ultimately cause chronic pancreatitis as evidenced by the established association between hyperparathyroidism and chronic pancreatitis. The most likely mechanism is thought to be recurrent acute pancreatitis progressing to chronic disease (necrosis–fibrosis theory). Another mechanism that has been suggested is protein plug formation by the hypercalcaemia (obstructive theory). The prevalence of acute and chronic pancreatitis is increased in patients with renal failure although the pathological reason for this association remains unknown, but has been variously attributed to (1) uraemic toxicity, (2) recurrent volume contraction during haemodialysis, (3) recurrent acute pancreatitis from secondary hyperparathyroidism and (4) alteration of the gastrointestinal hormone profile causing pancreatic exocrine dysfunction.

It is likely that the idiopathic category of chronic pancreatitis will ultimately be dropped as a result of progress in genomic studies identifying defect genes which predispose to the postnatal development of chronic pancreatitis following exposure to environmental and immune-mediated risk factors. Currently, idiopathic pancreatitis accounts for 10–30% of patients and is classified as early and late onset, with early-onset idiopathic chronic pancreatitis presenting in the first two decades of life with severe abdominal pain, and pancreatic insufficiency developing much later after several years. In contrast, late-onset idiopathic chronic pancreatitis, encountered in the fourth or fifth decade, presents with minimal pain, but with established pancreatic insufficiency at the time of diagnosis. Exocrine and endocrine insufficiency and pancreatic calcifications are much more commonly encountered in late-onset idiopathic chronic pancreatitis. The serine protease inhibitor Kazal type 1 (*SPINK1*) mutation has been found in many patients with early idiopathic chronic pancreatitis. The *SPINK1* gene encodes for the pancreatic secretory trypsin inhibitor, which normally counteracts the effects of activated trypsin. Mutations causing loss of function of this protein thus increase the risk of development of acute and chronic pancreatitis.

AIP also known as non-alcoholic duct-destructive chronic pancreatitis is rare, and many cases are labelled mistakenly as idiopathic chronic pancreatitis. AIP may occur in isolation or in association with other autoimmune disorders, e.g. Sjögren syndrome, primary sclerosing cholangitis, inflammatory bowel disease, etc. The clinical features of AIP include minimal pain, hypergammaglobulinaemia, autoantibodies (antinuclear antibody, antilactoferrin, anticarbonic anhydrase I and II, antismooth muscle), diffuse enlargement of the pancreas on CT imaging, absence of calcifications and cyst pseudocyst formation and marked improvement with steroid therapy. The histology of AIP shows diffuse fibrosis with infiltration of lymphocytes and plasmacytes, especially surrounding the pancreatic duct. ERCP/MRCP shows significant narrowing and irregularity of the pancreatic ducts. The pathogenesis of AIP is thought to result from immune-mediated damage to the pancreatic ductal cells. The cell infiltrates around the duct exhibit a distinct profile consisting of increased numbers of $CD4^+$ and $CD8^+$ T-cells.

Even one very severe episode of acute pancreatitis may result in permanent pancreatic damage with glandular fibrosis and hypofunction leading to chronic pancreatitis, but more commonly recurrent acute pancreatitis from any cause is responsible for the development of chronic pancreatitis through the necrosis–fibrosis pathway. The exceptions to this seem to be recurrent gallstone or hypertriglyceridaemia-associated pancreatitis, where progress to chronic pancreatitis is rare.

Obstructive pancreatitis is a separate category in the TIGAR-O and Marseille systems. Experimentally, obstruction of the main pancreatic duct produces changes of chronic pancreatitis within weeks in several animal models. The pathological features of obstructive pancreatitis in humans include uniform inter- and intralobular fibrosis and marked destruction of the exocrine parenchyma in the territory of obstruction, with absence of plug formation and calcifications. Pancreatic tumours (pancreatic adenocarcinoma, neuroendocrine tumours and intrapapillary mucinous tumours) can produce both recurrent acute and chronic pancreatitis as a result of duct obstruction. Obstruction of the main pancreatic duct leads to inspissation of the pancreatic juice which becomes lithogenic (with stone formation) and induces recurrent episodes of acute inflammation with periductular fibrosis. The pancreatic intraductal pressure is raised (ductal hypertension) and this is responsible for the pain of obstructive chronic pancreatitis and itself promotes fibrosis and glandular damage. In patients with large ducts, chronic hypertension results from stone and stricture formation. These patients require surgical or endoscopic decompression, which relieves the pain. Experimental studies have indicated that the pancreatic ductal hypertension is accompanied by reduced pancreatic blood flow and this is thought to play a role in the progression of fibrosis of the gland.

Surgical treatment of chronic pancreatitis

Maintenance of adequate nutrition, enzyme replacement and/or insulin supplements may be necessary in the management of exocrine and/or endocrine insufficiencies. The input of social services and of an interested psychiatric team is essential to manage drug addiction and alcoholic problems which are often present. Direct operative procedures on the parenchyma of the gland and/or its ductal system are indicated almost exclusively for the relief of pain. The limits and hazards of surgical treatment of these patients must be emphasized. No surgical procedure can restore either the endocrine or exocrine function of the pancreas. Nor is it likely to prevent further loss of glandular function. The conversion of a non-reformed alcoholic or drug addict into an insulin-dependent diabetic by major pancreatic resection is likely to be lethal and must be avoided. Rehabilitation of the patient must be planned well in advance otherwise surgical intervention for pain is doomed to failure. The life expectancy of the non-reformed alcoholic drug addict is extremely limited and is often shortened by the complications and late sequelae of operations. Avoidance of alcohol is a more important determination of outcome after operation than the type of procedure performed.

There are two indications for surgical treatment:

1. *Intractable pain* – it is crucial to delineate the frequency, persistence and degree of pain. The decision to advise operation is influenced by several factors including the degree of disruption of the patient's life, the narcotic need, the control of alcoholism, the age and general condition of the patient and, often, the surgeon's personal preferences.
2. *The development of complications* – these include (1) lower bile duct obstruction; (2) duodenal obstruction; (3) vascular involvement; (4) pancreatic cysts, pseudocysts, pancreatic ascites, and pleural effusions; and (5) the presence of a dominant mass leading to the fear or suspicion of cancer.

It is important to emphasize that correction of a complication does not invariably relieve any associated pain.

Lower bile duct obstruction

The lower portion of the common bile duct passes through the head of the pancreas and is at risk of being narrowed by inflammation and fibrosis in this region. If frank obstructive jaundice is present, the onus is on the surgeon to exclude preoperatively and operatively the presence of an underlying cancer. On occasions, this may only be possible after a total pancreatoduodenectomy. More commonly, the patient has low-grade cholangitis and pain indistinguishable from pancreatic pain. Frank suppurative cholangitis and secondary biliary cirrhosis have also been described. In the mild case, serum alkaline phosphatase elevation is the most consistent although non-specific effect of biliary obstruction. As a rule, investigation of the biliary tree (by MRCP/ERCP) is mandatory whenever surgical treatment of chronic pancreatitis is being considered. Relief of the partial common bile duct obstruction is, in some instances, all that is needed to relieve the pain.

Duodenal obstruction

This rarely occurs in patients with severe chronic pancreatitis and enlargement of the head of the pancreas. Here again a concomitant pancreatic cancer must be excluded by appropriate biopsies (in the young patient) or by pancreatoduodenctomy (in the older patient). Vagotomy and gastrojejunostomy will adequately relieve the duodenal obstruction.

Development of vascular complications

These include multiple pseudoaneurysms and sectorial portal hypertension. These have been discussed in the section on acute pancreatitis.

Once a decision for surgical treatment has been made, the two most important preoperative investigations are ERCP and angiography. ERCP will delineate the state of the main pancreatic duct and common bile duct and helps in the planning of surgical therapy. However, the findings on ERCP often do not correlate with the patient's symptoms. ERCP does not indicate the state of the parenchyma, nor does it indicate the need for operative intervention except if cytological examination of the pancreatic duct aspirate is positive for cancer. However, ERCP provides a good indication of the choice of operation. Similarly, angiography delineates the anatomy of the foregut vasculature as well as vascular complications which may necessitate an alteration in surgical strategy.

Although ERCP is often used as the gold standard for defining chronic pancreatitis, it is an invasive test that carries the risk of cholangitis and acute pancreatitis (approximately 4%). Angiography is also invasive and usually reserved for therapeutic embolization in cases of bleeding. Therefore, it is not surprising that MRCP and EUS are redefining the indications for ERCP and angiography in the evaluation of chronic pancreatitis. EUS allows viewing of the pancreas through the duodenal and gastric wall with high-frequency ultrasound probes, which are capable of much greater resolution of fine structural detail than conventional abdominal ultrasound. In addition, intestinal gas does not provide a barrier to the pancreas. Multiple criteria for the diagnosis of chronic pancreatitis have been proposed, including parenchymal changes described as hyperechogenic foci, hyperechogenic stranding, lobularity of the gland and cyst formation. Ductal changes include hyperechoic thickening, irregularity, dilatation, visible side branches and calcified duct stones. The EUS technology has the limitations of being operator dependent, and therefore the exact role of its use in the diagnosis of chronic pancreatitis is not yet established as this requires long-term longitudinal studies and careful follow-up of patients with suspected mild disease.

As a general rule, surgery should be conservative when there is no endocrine or exocrine insufficiency and a dilated duct of Wirsung is present. Dilatation (diameter >3 mm) of the main pancreatic duct, with or without partial stenosis of the duct, at a number of points producing a 'chain of lakes' appearance may be associated with pancreatic stones in the duct. In this situation, longitudinal filleting of the main pancreatic duct and side-to-side anastomosis to a Roux-en-Y loop of the jejunum (modified Puestow operation) is highly appropriate after removing any stones if present. Relief of pain is accomplished in about 70% of patients who stop consuming alcohol, although recurrence of pain is common after variable intervals. Surgery should be radical when pancreatic cancer is suspected and/or cannot be excluded, there is established endocrine and exocrine insufficiency and there is extensive pancreatic destruction by ductal sclerosis, glandular fibrosis, calcification and multiple pseudocysts.

A single pseudocyst may be drained internally as a preliminary step to see if the patient's pain is relieved. The presence of multiple cysts or the reformation of cysts is an indication for pancreatic resection. The 95% distal pancreatectomy (Child's procedure) is not uniformly successful, and recurrent pain associated with pancreatitis in the region of the head and the uncinate process then necessitates a second-stage pancreatoduodenectomy which can be technically difficult and hazardous. When pancreatic cancer is not suspected, total pancreatectomy can be performed in one stage with preservation of the whole stomach, pylorus and first part of the duodenum by careful preservation of the blood supply to the pyloroduodenal area. This diminishes postoperative problems associated with reduced gastric reservoir capacity and dumping syndrome.

Because 40–60% of patients with painful chronic pancreatitis exhibit a ductal ectasia, decompression of the pancreatic ductal system has become one of the main therapeutic principles, based on the established association between ductal ectasia and intraductal hypertension. Many different approaches to decompressing the pancreatic duct have been described. In 1956, Puestow and Gillesby described a technique in which drainage of the main pancreatic duct was accomplished by performing a longitudinal laterolateral pancreaticojejunostomy after resection of the pancreatic tail and splenectomy. Although the procedure met with some success, 15–40% of patients did not experience permanent pain relief. In an effort to improve results with drainage alone, several surgeons, including Beger and Frey, have combined resection with drainage. The Beger procedure includes a subtotal resection of the pancreatic head following transection of the pancreas anterior to the portal vein. The gastroduodenal passage and common bile duct continuity are preserved. The body of the pancreas is drained by an end-to-end or end-to-side pancreaticojejunostomy using a Roux-en-Y loop. The Frey procedure differs from the Beger in that there is no transection of the pancreas in front of the portal vein. For reconstruction, a longitudinal pancreaticojejunostomy is used draining the resection cavity of the head, body and tail of the pancreas.

A less radical approach which has been reported to be occasionally successful is the performance of a truncal vagotomy, antrectomy and gastrojejunal (Billroth II or Pólya) anastomosis. The rationale of this operation is the elimination of neural and hormonal stimuli to pancreatic secretion, especially those normally triggered by eating. No convincing data are available to support these contentions. Two other operations, namely cholecystectomy (for established gallbladder disease) and parathyroidectomy (for proved hyperparathyroidism), are sometimes advocated to reduce the severity of chronic pancreatitis. The incidence of gallstones in patients with chronic pancreatitis is the same as that in the general population. Cholecystectomy should be advised based on symptoms of gallbladder disease and on the risk of complications. It will not affect the natural history of chronic pancreatitis. Similarly, hyperparathyroidism should be treated to avoid the sequelae of severe hypercalcaemia without influencing the course of any incidental chronic pancreatitis.

Splanchnic neurectomies and coeliac ganglion block have generally been disappointing in the control of chronic pancreatic pain.

First reported in 1943, splanchnicectomy for the management of intractable pancreatic pain was practically forgotten because of the invasiveness required (laparotomy or thoracotomy in patients with limited survival) and the inconsistent results achieved. With the evolution of minimal access surgery, however, interest has been rekindled. The first thoracoscopic splanchnicectomy for pancreatic cancer pain was performed in 1993 and was soon followed by numerous other reports advocating its use for chronic pancreatitis pain. In this procedure, four trocars are optimal: camera, lung retraction and two working ports.

After transecting the inferior pulmonary ligament, the lung is retracted anteromedially. The sympathetic trunk is identified as a guide to the greater splanchnic nerve, which lies medial to it close to the aorta on the left and the oesophagus on the right. The overlying pleura is incised and the nerve is dissected free and transected sharply. Left-sided splanchnicectomy alone seems effective in most patients. Preliminary studies indicate that the procedure is effective, but long-term follow-up is lacking at the present time. Promising results have been obtained recently with thoracoscopic bilateral splanchnicectomy although the reported experience is limited and the follow-up short.

Neoplasms of the non-endocrine pancreas

Benign neoplasms of the non-endocrine pancreas are exceedingly rare and are of no clinical significance unless they become large enough to be palpable or to impinge on adjacent structures (common bile duct, duodenum, stomach or main pancreatic duct) and cause symptoms. Since both solid and cystic benign tumours are rarely found at laparotomy or at necropsy, there is no evidence to suggest that they represent an early phase in the development of the more common malignant neoplasms. The reported benign tumours of the non-endocrine pancreas include adenoma, cystadenoma, lipoma, fibroma, leiomyofibroma, myoma, haemangioma, lymphangioma, haemangioendothelioma and neuroma. These diagnoses should only be made after exclusion of the more frequent malignant tumours by some form of representative (preferably excisional) biopsy.

Pancreatic cancer

The term ‘pancreatic cancer’ is sometimes used to include all types of malignant neoplasms of the non-endocrine pancreas (Box 27.3) as well as malignant islet cell tumours (Table 27.6).

In clinical practice, pancreatic cancer is synonymous with PDAC (arising in the exocrine pancreas), which constitutes 90% of all primary malignant tumours arising from the gland. When the cancer originates in the head of the pancreas (in about 70% of cases) it must also be differentiated from cancer arising from the ampulla, duodenum or lower common bile duct, which has a much better prognosis than true pancreatic adenocarcinoma. The incidence of pancreatic cancer has tripled over the past 40 years throughout the West. It is highly fatal and has one of the lowest 5 year survival rates (1–2%) of all cancers. About 29 000 new pancreatic cancers are diagnosed each year in the USA and the disease now accounts for 10% of all the cancers of the digestive tract (second behind colorectal cancer). It is the fourth most common cancer of all sites as a cause of death (behind lung, colorectal and breast).

Cancer of the pancreas is distinctly more common in older people and is relatively uncommon, but not altogether rare, below the age of 55 years. It occurs more frequently in men than in women but the male-to-female ratio has decreased in recent years, suggesting that more women are now being diagnosed with this cancer. The exact causative factors responsible for the increase in incidence of pancreatic cancer are unknown. A high-protein and high-fat diet, characteristic of the Western population, has been implicated epidemiologically as a possible factor. The strongest association is between pancreatic cancer and cigarette smoking. Exposure to industrial carcinogens, especially betanaphthylamine and benzidine, has been documented in pancreatic cancer patients. A higher than normal incidence rate of the neoplasm has also been reported in chemists, workers in metal industries, and coke and gas plant employees. In interpreting these retrospective epidemiological data, it must be remembered that the general class of ‘labourer’ has, both in the USA and in Britain, an excessively high incidence of pancreatic cancer so that occupational risk is mixed with social class risk. Industrial causes of pancreatic cancer are probably less important than is believed, or the causative exposures are far more widespread in most occupations than is generally accepted.

BOX 27.3 Pathological classification of primary malignant neoplasms of the pancreas (non-endocrine)

1. Duct (ductular) cell origin 90%
- Duct cell adenocarcinoma
- Giant cell carcinoma
- Giant cell carcinoma (epulis-osteoid)
- Adenosquamous carcinoma 10%
- Microadenocarcinoma
- Mucinous (colloid) carcinoma
- Intraduct papillary mucinous neoplasms

2. Acinar cell origin <1%
- Acinar cell carcinoma
- Cystadenocarcinoma (acinar cell)

3. Connective tissue origin <1%
- ‘Osteogenic’ sarcoma
- Leiomyosarcoma
- Haemangiopericytoma
- Malignant fibrous histiocytoma

4. Uncertain histogenesis 8%
- Pancreaticoblastoma
- Papillary and cystic neoplasm
- Mixed type: duct and islet cells
- Unclassified

5. Miscellaneous others <1%
- Malignant melanoma
- Oncocytoma
- Neuroblastoma
- Plasmacytoma
- Lymphoma

Molecular biology of pancreatic cancer

Sporadic cancers of the pancreas are frequently associated with the activation of an oncogene, K-*ras*, and the inactivation of multiple tumour suppressor genes, including *p53*, *DPC4*, *p16* and *Rb*.

Oncogenes of the *ras* family (e.g. H-*ras*, N-*ras* and K-*ras*) are among the most common activated oncogenes found in

Table 27.6 Islet cell tumours and associated clinical syndromes

Cell type	Peptide product	Tumour	Clinical picture
A cell	Glucagon	Glucagonoma	Diabetes, necrolytic migratory erythema, stomatitis, glossitis Weight loss, weakness
B cell	Insulin	Insulinoma	Neuroglycopenia Clouded sensorium Behaviour disturbance Seizures Transient neurological deficit Adrenaline discharge Sweating Tremulousness Palpitation Hunger
D cell	Gastrin	Gastrinoma	Fulminant peptic ulceration Diarrhoea Malabsorption
D-cell	Somatostatin	Somatostatinoma	Diabetes, pancreatic malabsorption with steatorrhoea, gallstones Weight loss
D_1-cell?	Vasoactive intestinal polypeptide	VIPoma	Fulminant diarrhoea, hypokalaemia, hypercalcaemia, diabetes, flushing
D_1-cell?	Human pancreatic polypeptide	HPPoma	Uncertain
9	ACTH	?	Cushing syndrome
?	Hydroxyindole	Carcinoid	Carcinoid syndrome?
?	Prostaglandin	?	Same as VIPoma?
9	ADH	?	?
?	None	Non-functioning islet cell tumour	Same as exocrine tumour but slow growing

ACTH, adrenocorticotrophic hormone; ADH, antidiuretic hormone.

human cancer. The K-*ras* gene, on chromosome 12, encodes a 2.0 kb transcript that is highly conserved across species and is translated into the p21–ras protein. These proteins are located in the plasma membrane and transduce growth and differentiation signals from activated receptors to protein kinases within the cell. Up to 90% of human pancreatic cancers have *ras* gene mutations, most of which are K-*ras* mutations and these seem to be an early event in pancreatic carcinogenesis.

The *p53* gene is the most frequently mutated gene identified in human cancers. The *p53* tumour suppressor gene encodes a 393 amino acid phosphoprotein that acts as a potent transcription factor regulating many cellular functions and has been called the ‘guardian of the genome’ because its role is to induce apoptosis (cell death) when an abnormality cannot be repaired. It inhibits oncogene-induced transformation, blocks progression through the G1 phase of the cell cycle, modulates the expression of growth control genes and maintains genome stability. Mutations in the *p53* gene result in an abnormal protein unable to carry out its regulatory functions, leading to cell transformation and neoplasia. A number of studies have indicated that *p53* mutations are relatively common in adenocarcinoma of the pancreas, occurring in 70% of patients. In addition, *p53* mutation may be an independent prognostic factor in patients with PDAC.

The *pl6* gene, which is located on chromosome 9p, encodes a protein that binds cyclin D–cdk4 complexes. When *pl6* binds to these complexes, it inhibits the phosphorylation of a number of growth and regulatory proteins, including the retinoblastoma protein (Rb). Hypophosphorylated Rb binds to and sequesters transcription factors that would otherwise promote the Gl/S transition in the cell cycle. Inactivation of *pl6* therefore inactivates another important cell cycle checkpoint. Mutations in the *p16* gene are found in approximately 60% of pancreatic adenocarcinomas and may be associated with short patient survival.

The tumour suppressor gene *DPC4* (deleted in pancreatic carcinoma, locus 4) resides on chromosome 18q and has homology to a family of proteins called the Mad proteins which play a role in signal transduction for the transforming growth factor (TGF)-β family of cell surface receptors. TGF-β can downregulate the growth of epithelial cells and stimulate differentiation and apoptosis. Therefore, it is reasonable to expect that the loss of DPC4 would promote cell growth. DPC4 is inactivated in approximately half of all pancreatic cancers and, in contrast to *p53* and *p16*, appears to be relatively specific to pancreatic cancer.

Pancreatic intraepithelial neoplasia

It is now believed that invasive pancreatic ductal carcinoma arises from precursor ductal lesions referred to as pancreatic intraepithelial neoplasia (PanIN) and are grouped into three histological grades of increasing degrees of architectural and nuclear atypia (PanIN1a,b, PanIN2, PanIN3). PanINs have led to a better understanding of the sequential molecular changes leading to invasive ductal adenocarcinoma (PDAC) and their study has identified loss of heterozygosity at a number of loci and for alterations in a number of abnormal genes and proteins that are commonly found in pancreatic carcinomas, e.g. K-*ras*, *HER-2/neu*, *p16*, *p21*, *p53*, *DPC4* and *BRCA*. These studies have confirmed that PanINs accumulate genetic changes of increasing atypia, supporting the theory that they are the precursors of PDAC.

S100P has been identified among the genes expressed in PDAC and pancreatic tumour cell lines. S100P is a member of the S100 family of EF-hand, calcium-binding proteins which have a variety of functions and target proteins. S100P is upregulated in intraductal papillary mucinous neoplasms. S100P binds with a protein, S100P–BPR, the interaction being dependent on Ca^{2+} and Mg^{2+} and results in conformational changes in S100P with exposure of its hydrophobic surfaces. S100P–BPR is located at 1p34.3. S100P–BPR is a widely expressed protein and is present in pancreatic islets together with S100P, but neither protein is expressed in normal ductal cells. In contrast, both S100P and S100P–BPR are overexpressed in PanINs and PDAC samples. Furthermore, the overexpression of S100P correlates significantly with increasing grade of PanIN lesions. The similarity in the expression patterns of these two proteins, in healthy pancreas and in PDAC, supports the view that their upregulation is involved in the development of pancreatic cancer. As not all PanINs progress to malignant disease, further studies are needed to identify the genes that determine which high-risk PanINs are likely to progress to invasive PDAC. Alterations in the sequence or expression levels of K-Ras, HER2/neu, p16INK4a, BRCA2, p53, DPC4, cyclin D1, and p21 have previously been described in these precursor lesions. Marked overexpression of S100P in PDAC has been well documented. Its expression in PanIN-1A lesions is low (2%) but increases significantly to 13% in PanIN-1B, 31% in PanIN-2 and 41% in PanIN-3 lesions.

K-Ras activation and overexpression of HER2/neu are the earliest changes in precursor lesions as they are observed in PanIN-1A and PanIN-IB. These changes are followed by an increase in the number of p21-expressing lesions (32% of PanIN-1B are positive for p21) and this is thought to be a direct result of Ras activation or HER2/neu overexpression. S100P expression is one of the genes whose expression is altered very early in the development of PDAC, whereas loss of p16 is observed slightly later (PanIN-2 and -3). Altered p53 expression, cyclin D1 elevation, decreased DPC4, and BRCA2 loss of heterozygosity are later aberrations and occur at a lower frequency. Expression of S100P is twice as prevalent in invasive PDAC (92% of cases) as in PanIN-3 lesions (41% of cases), suggesting that S100P may play an important role in progression from PanINs to invasive PDAC. Thus S100P may prove to be a valuable marker for the prediction of clinically relevant PanINs, i.e. those which are likely to progress to invasive malignancy and thus require intervention.

Pancreatic cancer and diabetes mellitus

There is no doubt that there is an association between pancreatic cancer and diabetes mellitus. Two hypotheses have been put forward. First, diabetes mellitus is an aetiological factor in the development of pancreatic cancer. The evidence for this theory is rather confusing. When recent diabetes was eliminated, some studies found as high as a sixfold risk for pancreatic cancer in diabetic women but not in diabetic men. Several uncertainties result from the fact that there has been no strict delineation of the type of diabetic who is prone to develop pancreatic cancer and no sorting out of the genetic aspects of the disease in the population studied. In addition, there have been varying definitions of diabetes in all reported studies. We therefore do not know if all diabetics or a special subset are at risk from pancreatic cancer. It may well be that diabetics have so many other complications that few actually live long enough to develop pancreatic cancer.

The second hypothesis is that the presence of pancreatic cancer in some way induces glucose intolerance. This is supported by the fact that in many cases the diabetes is diagnosed within 2 years before the cancer is discovered. Thus, there may be two types of diabetes mellitus in pancreatic cancer patients: (1) individuals in whom the hereditary type is present with its possible increased risk of pancreatic cancer and (2) patients in whom the hyperglycaemia is of shorter duration and is a result of the pancreatic cancer. There is a definite suggestion of a bimodality of duration of clinical diabetes mellitus in several series of pancreatic cancer patients (40% of patients with duration of greater than 2 years, and 50% with duration of less than 1 year).

Alcoholism and chronic pancreatitis

Retrospective epidemiological data regarding an association between alcoholism and pancreatic cancer are inconclusive. As with diabetics, alcoholics have so many other problems that pancreatic cancer is one of their lesser worries. The main reason for considering an alcohol–pancreatic cancer association is that pancreatitis (which can be induced by alcohol) has been associated with pancreatic cancer. However, it must be emphasized that 'pancreatitis' may have three different meanings: (1) histological pancreatitis invariably coexists with pancreatic cancer, presumably due to ductal obstruction and/or direct destruction of parenchymatous tissues; (2) the acquired variety of chronic pancreatitis (clinical entity) does not seem to be related to pancreatic cancer; and (3) the hereditary type of chronic pancreatitis seems to have a higher predisposition to pancreatic cancer than the general population.

Cancer of the head of the pancreas

This has to be differentiated from cancer of the ampulla, lower common bile duct and/or duodenum since these latter tumours may present with similar features. The term 'periampullary carcinoma' is often used to denote tumours in this region irrespective of the exact site of origin. Progressive jaundice occurs in over 75% of patients with carcinoma of the head of the pancreas and the incidence of jaundice decreases as the location of the lesion progresses to the left towards the tail of the pancreas. Occasionally, a tumour may invade and compress the third or fourth parts of the duodenum without actually obstructing the common bile duct. Pain is extremely frequent and the classic description of painless jaundice is rarely encountered. Weight loss and anorexia are also common symptoms even in early stages. Nausea, epigastric bloating, change in bowel habits and vomiting are occasionally present. Haematemesis and melaena occasionally occur in late cases as a result of direct invasion of the duodenal or gastric mucosa by tumour or superior mesenteric–splenic vein compression by the tumour. Chills and fever due to cholangitis can occur in longstanding biliary obstruction. A palpable gallbladder (Courvoisier's sign) is noted in only about a quarter of patients with resectable tumours. The liver is usually enlarged on palpation.

Cancer of the body and tail of the pancreas

Pain and weight loss are the two main consistent symptoms. The pain may initially be dull and vague, localized to the epigastrium or to the back, or it may move to either upper quadrant. It may be episodic and related to meals or it may become constant and severe. In late cases, the patient learns to obtain partial relief by flexing the trunk forward. Severe pain invariably indicates extension of tumour into the perineural lymphatics and the posterior parietes. Weight loss is rapid and severe by the time the patient presents to the hospital. Again, haematemesis and melaena may be late features due to mucosal invasion or portal hypertension. Migratory thrombophlebitis (Trousseau's sign) can be present in any patient with advanced cancer, is not specifically indicative of pancreatic carcinoma and, by itself, does not merit diagnostic laparotomy or laparoscopy.

Physical examination in the early stages may reveal surprisingly few abnormal physical signs. In late cases, abdominal masses or liver metastases may be palpable. A rectal shelf may be evident on rectal examination in the rectovesical or rectovaginal pouch (Blumer's shelf), there may be evidence of ascites and distant metastases may be present in the supraclavicular fossa (Troisier's sign).

Delay in diagnosis

Over 90% of patients with pancreatic cancer present in the late stage of their disease at a time when there is no chance of cure and, often, even meaningful palliation cannot be achieved. The factors responsible for late diagnosis are listed below.

- The tumour is asymptomatic in the early stages. There is some evidence that the preclinical phase of pancreatic cancer may be present for months or even years before the tumour 'appears'.
- 'Patient delay' – the early symptoms are often vague and non-specific and the patient tolerates the discomfort.
- 'Physician delay' – the physician often does not have a high index of suspicion and fails to properly 'evaluate' the patient in the face of a vague history and normal physical examination.
- The patient may not have ready and easy access to competent diagnostic centres. Centralization or regionalization of the management of difficult pancreatic problems is long overdue because of the dependence on sophisticated diagnostic and therapeutic methods.

Positive physical signs in a patient with pancreatic cancer often reflect incurability. The diagnosis therefore needs to be made before the appearance of abnormal physical signs. The clinician should always consider the diagnosis of pancreatic cancer in any patient presenting with seemingly genuine recent symptoms, absent physical signs and negative routine radiological investigation. These are the very patients in whom maximum benefit may be gained by applying the more sophisticated investigative techniques.

Evaluation of diagnostic tests

It is no great triumph to diagnose incurable advanced pancreatic cancer. Any particular technique must be assessed on its ability to diagnose potentially curable lesions of the pancreas. A rational sequence of testing is as follows. CT is the best initial test in the evaluation of a patient with suspected pancreatic cancer. Thin section multidetector helical angio-CT scanning through the pancreas with an intravenous bolus injection of contrast can delineate the pancreatic mass, the relationship of the tumour to the superior mesenteric artery and vein and to the coeliac axis, the patency of the portal vein, and the presence of distant metastastic disease.

Until recently, ERCP combined with cytology has been used to differentiate choledocholithiasis from malignant obstruction of the distal common bile duct when a mass is not seen on CT. With the advent of EUS, the rare but real complication of pancreatitis secondary to injection of contrast into the pancreatic duct during ERCP may be avoided. However, EUS requires a dedicated and skilled endoscopist with the appropriate equipment to be successful and may not be available at all medical centres.

It has become obvious that the diagnosis of *advanced* pancreatic cancer can be made after a careful history and routine physical examination. If obvious metastases are present such as seedings in the retrovesical pouch or the pouch of Douglas on rectal or pelvic examination or large left supraclavicular nodes (Troisier's sign) and/or obvious nodular hepatomegaly, careful consideration should be given in avoiding prolonged and unnecessary investigations and even a diagnostic laparotomy. This logic pertains especially to cancer of the body and tail of the pancreas which is rarely, if ever, curable in a symptomatic patient. Percutaneous needle biopsy of any accessible lesion, including the pancreatic mass, can achieve the diagnosis in many cases and the duration of hospitalization can be appreciably shortened. The frail elderly patient with clinically obvious cancer of the body or tail of the pancreas should be spared the mortality and morbidity of a diagnostic laparotomy. Direct percutaneous needle aspiration of the mass with ultrasound or CT scan for guidance should be attempted (Figures 27.20 and 27.21). Another way of obviating laparotomy in these seriously ill people is to perform laparoscopy and direct vision biopsy.

ERCP with stent placement can be performed if the patient is jaundiced, or, if the patient is fit and relatively young, exploration with a view to internal biliary drainage should be performed as described later. The technology of imaging methods is advancing rapidly: 3.0 T MRI, multidetector helical angio-CT with the ability for both image segmentation and 3D volume imaging of the pathology, high-frequency EUS and positron emission tomography (PET) scanning appear to be the

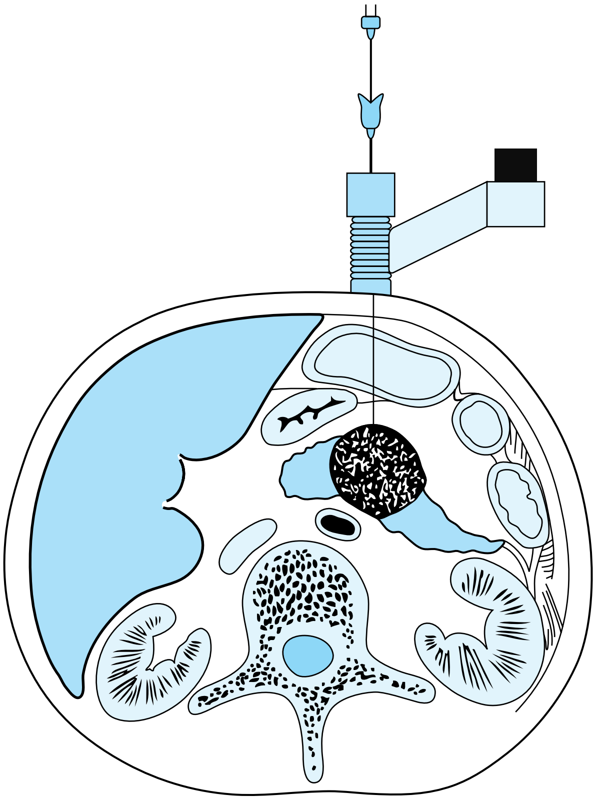

Figure 27.20 Schematic representation of the percutaneous fine needle aspiration technique of a pancreatic mass under ultrasound or CT scan control. The aspirated material is smeared on glass slides and fixed and stained by the Papanicolaou or Giemsa method for microscopic examination.

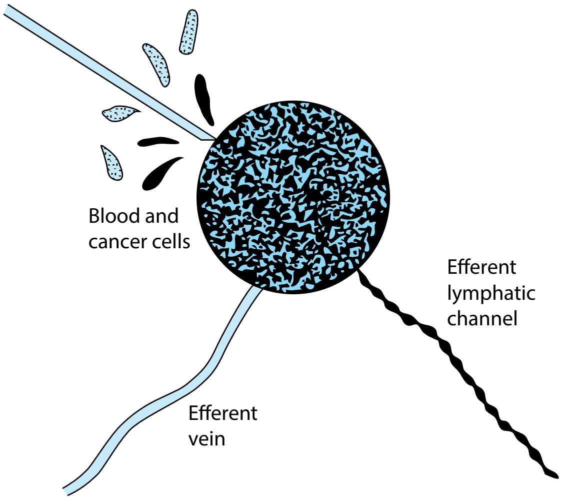

Figure 27.21 Aspiration 'biopsy' and tumour seeding. Seeding of tumour cells occurs experimentally but is probably of no clinical significance in advanced cases.

way of the future, although they are likely to be restricted to specialized regional high-volume centres.

Positron emission tomography scanning

The published evidence suggests that PET imaging is very useful after surgery to detect locoregional recurrence or distant metastases when the follow-up levels of the tumour markers become elevated as PET detects viable metabolically active tumour (as distinct from scarring and other postsurgical benign changes) and which no other imaging modality can. Some surgeons also use PET in the preoperative work-up, especially when the CT or MRI provides inconclusive reports.

PET scan parameters such as maximum tumour standardized uptake value (SUV_m) and the product of tumour SUV and volume [metabolic tumour burden (MTB)] have been shown to correlate with survival. One study on 56 patients with unresectable pancreatic cancer treated with a single fraction of 25 Gy stereotactic body radiotherapy and gemcitibine-based chemotherapy showed that SUV_m and MTB correlated with survival. The subgroup with both lower SUV_m and lower MTB showed a trend towards longer survival with a median of 18.7 months.

Surgical treatment of pancreatic cancer

Emphasis must be placed on preoperative evaluation and adequate preparation of the patient with pancreatic cancer. As mentioned earlier, CT scan, EUS and, in some instances, ERCP and FNA for cytology provide the surgeon with valuable preoperative information and obviate the need for time-consuming manoeuvres on the operating table. It cannot be overemphasized that pancreatic exploration with a view to resection should not be performed by the occasional surgeon or the resident registrar in training or in institutions where there is not all the back-up expertise (endoscopy, radiology, cytology, endocrinology) necessary for the care and management of these difficult problems.

Preoperative preparation

All jaundiced patients must be kept in a good state of nutrition and hydration with supplemental intravenous fluids, elemental diet and multivitamins as deemed necessary. Injudicious use of intravenous contrast for CT scanning may precipitate renal failure, which can also occur postoperatively due to hypovolaemia. A continuous diuresis must be maintained at all times. If the patient is grossly malnourished, a period of parenteral hyperalimentation both before and after operation may be beneficial.

Blood-clotting deficiencies must be corrected. Anaemia is corrected by blood transfusion. Daily injections of vitamin K are administered, preferably for 4–5 days prior to operation. Six units of fresh frozen plasma, six units of platelets and at least six units of blood should be made available. It must be emphasized that pancreaticoduodenectomy can now be safely performed without blood transfusion in many instances.

Cardiopulmonary function should be carefully assessed by pulmonary function tests, chest radiograph and ECG as deemed necessary. Smoking is prohibited. Intensive pulmonary physiotherapy, active mobilization and leg exercises are strongly encouraged preoperatively. The question of prophylactic digitalization and diuretic therapy is considered in individual patients to achieve maximum cardiovascular compensation.

If a patient is critically ill with one or more of the following parameters, (1) a highly elevated serum bilirubin (greater than 200 μm/L (12 mg%); (2) sepsis; (3) hepatorenal failure; (4) severe cardiopulmonary disease which is expected to respond to medical management; or (5) severe malnutrition, a percutaneous transhepatic or endoscopic biliary decompression may be attempted to tide over the patient for 2 or 3 weeks until his/her general condition improves adequately for him/her to be considered for a major pancreatic resection. If the technique of percutaneous biliary drainage or endoscopic stenting is not available, a simple cholecystostomy using ultrasound for guidance may be undertaken under local anaesthesia. However, routine biliary preoperative decompression is *not* recommended as it increases the postoperative mortality and morbidity and should be undertaken only if the patient has septic cholangitis.

Selection of patients for pancreatic resection

Except in unusual circumstances, a major pancreatic resection is inadvisable in (1) elderly people (older than 80 years), (2) frail patients with multiple systemic disorders and (3) those with an estimated life expectancy of less than 3 years. The operation should be reserved for the relatively fit patient under the most favourable circumstances. The surgeon must use clinical judgement in the determination of the relative indications and contraindications for each procedure. The operative mortality should not exceed 5%. A frank discussion must take place between the surgeon, the patient and his or her relatives prior to embarking on a potentially hazardous operation.

Surgical options

For curative surgical treatment of a cancer in the head of the pancreas, four options are available.

1. The Whipple operation (pancreaticoduodenectomy), in which the head and neck of the pancreas together with the duodenum, the distal half of the stomach, lower common bile duct and gallbladder and upper jejunum are removed with as much of the regional lymph nodes as possible.
2. Pylorus-preserving pancreaticoduodenectomy as introduced by Traverso and Longmire in 1978 in an attempt to eliminate the postgastrectomy symptoms seen with antrectomy. This operation technically differs from the standard Whipple procedure only in the preservation of the blood supply to the proximal duodenum.
3. Total pancreatectomy (total pancreaticoduodenectomy) includes, along with the contents of the Whipple operation, excision of the spleen, body and tail of the pancreas, and a more thorough regional lymphadenectomy.
4. Regional pancreatectomy as proposed by Fortner entails extirpation of the transpancreatic portion of the portal vein, the coeliac axis, the superior mesenteric artery and the middle colic vessels, together with structures included in a total pancreatectomy.

Of these four alternatives, the Whipple operation is most commonly employed for tumours of the head of the pancreas. The operation is optimal for malignant tumours that are confined to the duodenum, ampulla of Vater or lower common bile duct. The neck of the gland is divided to the left of the superior mesenteric vein and the body and tail of the pancreas and spleen are left undisturbed. *En bloc* excision of the regional lymph nodes from the porta hepatis, aortocaval and superior mesenteric regions again forms part of the operation. With the Whipple operation, diabetic function can be preserved. Although there is the possibility of an anastomotic leak from the pancreaticojejunostomy, this complication occurs in less than 10% of patients at centres experienced with pancreatic surgery. Also, more effective management of pancreatic anastomotic leakage with hyperalimentation, percutaneous drainage and somatostatin analogue has reduced the magnitude of this problem. Total pancreatectomy should be reserved for situations when there is tumour at the pancreatic margin on serial frozen sections or if the pancreas is not suitable for an anastomosis, especially if the patient is already an insulin-requiring diabetic. A pylorus-preserving Whipple operation is a reasonable alternative but may result in transient gastric stasis.

The concept of extended resection for pancreatic cancer with resections of one or more of the major vessels (regional pancreatectomy) is uniformly attended by an increased morbidity and mortality without a concomitant improvement in cure rate. When such extensive procedures are needed to resect the local tumour, occult metastatic disease is usually present and the disease is incurable. Several authors have advocated a selective approach to venous resection when the lesion has been deemed resectable, the pancreatic neck is divided, and while dissecting the uncinate process from the superior mesenteric vein the tumour is found to be adherent to the posterolateral portion of the vein. The venous segment can be replaced with an internal jugular vein interposition graft. It must be emphasized that resection of the portal–superior mesenteric venous axis is only recommended if it is relatively minor (less than 1 cm in length and less than half of the venous circumference) and it helps in achieving adequate clearance of soft tissue margins.

Operative diagnosis of pancreatic cancer and its differentiation from chronic pancreatitis

The jaundiced patient nowadays is well investigated preoperatively and usually a diagnosis is made prior to laparotomy. A general rule is as follows: hard, non-cystic masses in the head of the pancreas which are associated with obstructive jaundice and dilatation of the common bile duct are usually carcinoma, especially if acute inflammation and/or gallstones are absent. Conversely, hard, non-cystic masses involving a major part of the retroampullary part of the gland and unassociated with jaundice or dilatation of the biliary tree are usually pancreatitis.

It is important to remember that pancreatitis of varying degree invariably coexists with all carcinomas and that patients with gallstones may have a concomitant pancreatic cancer. In doubtful situations, the surgeon must decide whether to try to establish a tissue diagnosis by frozen section histology of biopsies prior to assessing resectability of any pancreatic mass. Every surgeon is influenced by his own philosophy, his experience and expertise, his pathologist's experience and by the clinical situation. Hence, any decision in such a clinical setting can easily lead to controversy when discussed retrospectively or hypothetically. The author's general policy about pancreatic biopsy can be summed up as follows. (1) Since over 75% of all cancers in the head of the pancreas are identified preoperatively by a positive cytology (at ERCP or percutaneous biopsy), it is preferable to assess the resectability of all such masses in the first instance. If conditions are favourable, they are resected without a preliminary biopsy. (2) A suspected cancer of the body and tail of the pancreas is 'biopsied' by a distal pancreatectomy and splenectomy provided that the lesion is localized and resectable. If frozen section histological examination reveals a cancer, the 'excision biopsy' is converted to a total or near-total pancreatectomy with regional lymphadenectomy. (3) All unresectable and/or metastatic tumours of the pancreas are diagnosed before the surgeon leaves the operating room even if the job is time consuming. This takes the matter out of the realm of doubt, an especially important point when a palliative procedure restores the patient to relatively good health for a long period and doubt is raised as to the true diagnosis. A known positive biopsy for adenocarcinoma of the pancreas will then prevent a fruitless second laparotomy. (4) Frozen sections and histological examination of lymph nodes peripheral or adjacent to delineated pancreatic masses are acceptable if unresectability and/or the presence of metastatic disease is documented. However, a positive regional node *per se* is not an absolute criterion of unresectability. Many patients have survived longer than 3 years following pancreatoduodenectomy in the presence of regional lymph node involvement.

This policy is supported by the following arguments.

- Truly representative needle biopsies of the pancreas are often hard to obtain because of sampling error and confusion between tumour and associated pancreatitis (Figure 27.22).
- The establishment of diagnosis by frozen section histology is sometimes time-consuming and traumatic. Factors which influence the biopsy policy of surgeons include personal experience of complications, interpretative histological errors and traditional teaching. Many senior surgeons still regard pancreatic biopsy as inaccurate and dangerous. Pancreatitis, fistula formation, haemorrhage and infection have all been reported following all biopsy techniques. However, it is often difficult to decide whether such complications are directly attributable to the biopsy itself or to the concomitant surgical manoeuvres and manipulations. The consensus of opinion is that all surgeons involved in the practice of pancreatic surgery should be willing and able to perform pancreatic biopsy safely if it is indicated. When this is done, the surgeon should make great efforts to avoid major pancreatic ducts and vessels. A good Kocher manoeuvre between the fingers and thumb of the left hand will guide the biopsy needle through the duodenum into the appropriate suspicious area of the pancreas. The disposable Travenol 'Tru-Cut' needle is very suitable for this purpose. A less traumatic alternative is to employ a long no. 21 needle, pushing it in a similar fashion through the duodenum, and attaching a 10 mL syringe for aspiration in order to provide a smear for cytology. This is gaining in popularity with the more widespread availability of, and co-operation with, skilled cytopathologists (Figure 27.23). Haemorrhage, when encountered, can be controlled by finger pressure. Occasionally, silk mattress sutures are needed for haemostasis of the pancreatic capsule following direct pancreatic puncture.
- Errors in interpretation of frozen section biopsy specimens of the pancreas are sometimes made by the inexperienced histopathologist because some desmoplastic carcinomas closely resemble chronic pancreatitis.

Assessment of resectability

A cancer of the pancreas is considered unresectable if there are distant (liver or peritoneal) metastases, invasion of major vessels (portal vein, hepatic artery, superior mesenteric vessels or coeliac axis) or any extension beyond the area of usual total pancreatectomy specimen. The possible exception is the case of isolated portal vein invasion provided the vein is patent. In these selected cases, portal vein resection with

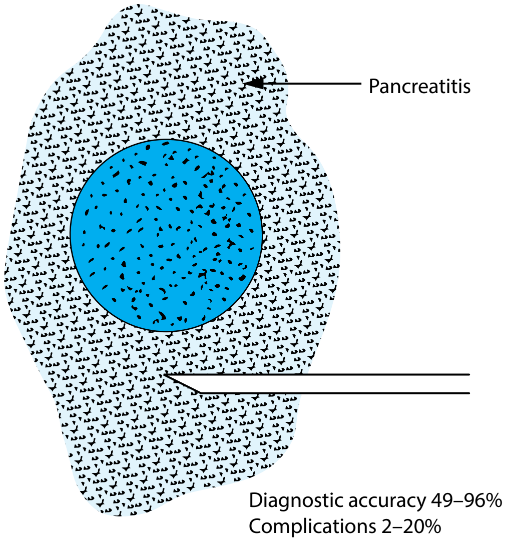

Figure 27.22 Peroperative pancreatic biopsy. A variable degree of pancreatitis surrounds any pancreatic cancer leading to a 'sampling error' with needle biopsies. The number of biopsies taken is limited because of potential morbidity and even mortality and the biopsies may miss the cancer altogether.

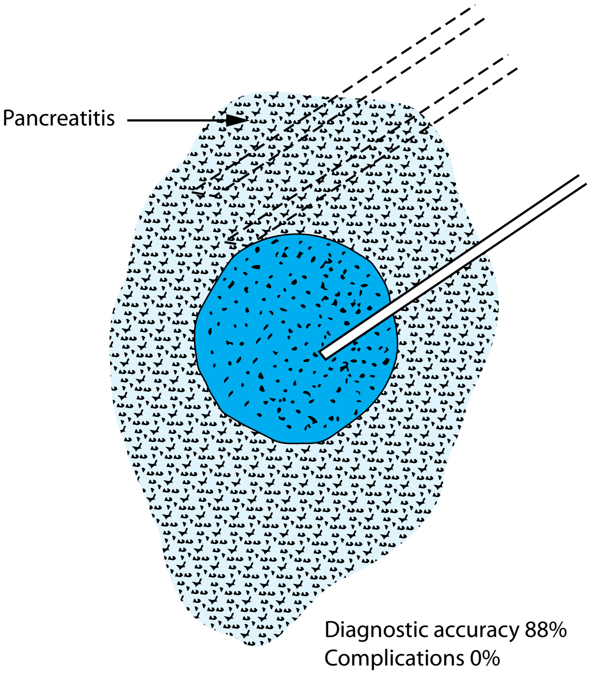

Figure 27.23 Fine-needle aspiration 'biopsy' for cytological examination. Multiple punctures may be performed with minimal risks and increase the chance of obtaining material from the cancer.

interposition venous graft placement has been described. Puckering of the transverse mesocolon *per se* does not always indicate unresectability since the transverse mesocolon and, if necessary, the transverse colon can be excised in a pancreatoduodenectomy specimen if there are no other contraindications to a resection.

Immediate postoperative care and complications

Following a major pancreatic resection, the patient should be transferred to an intensive care unit where experienced nursing care and sophisticated monitoring techniques are readily available. Patients may require respiratory assistance for the first 12–24 hours. For the first 3–4 postoperative days, the patient's blood sugar is checked every 3–4 hours and small doses of regular insulin (2–5 units) are given intravenously as boluses. Alternatively, a continuous intravenous infusion of insulin can be given. It is important to maintain the blood sugar between 75 and 150 mg% (4–8 mmol/L).

Haemorrhage is still the commonest intraoperative and postoperative complication encountered with pancreatoduodenectomy or total pancreatectomy. However, the incidence of this complication has decreased from about 10% to less than 1% in experienced hands. Meticulous preoperative preparation, careful haemostasis, and adequate replacement of blood and clotting factors during the operation are essential. In spite of these precautions, the patient may occasionally continue to bleed at a fairly alarming rate from all raw areas in the abdominal cavity during the first 24 hours. The indications for reoperation are:

- if there is reason to suspect a major bleeding site
- when clot accumulation in the abdomen causes distension and tamponade
- when a consumption coagulopathy is recognized.

In most cases a discrete bleeding point is never found at reoperation. The clots are gently evacuated and the whole abdomen is irrigated prior to closure with drainage. Haemobilia following biliary decompression is not unusual. It invariably stops spontaneously. Whenever haemorrhage is suspected, the patient must be kept normovolaemic by adequate blood and fluid replacement and by maintaining a continuous diuresis. Intermittent doses of diuretics may be given as necessary. Hepatorenal failure is the commonest sequence of events leading to postoperative death in this group of patients.

Other complications which may also be fatal include sepsis, mesenteric thrombosis, uraemia, liver insufficiency, myocardial infarction, cerebrovascular accident, congestive heart failure and pulmonary embolism. Leakage from the biliary enteric anastomosis or from the gastrojejunostomy are largely preventable by careful and proper construction of both anastomoses. Anastomotic leaks from the pancreaticojejunostomy occur in less than 10% of patients at centres experienced with pancreatic surgery. Management of pancreatic anastomotic leakage with hyperalimentation, percutaneous drainage and somatostatin analogue has reduced the magnitude of this problem. Complications that are usually non-fatal include pneumonitis, gastric retention, paralytic ileus, bowel obstruction, wound infection, wound dehiscence, atrial fibrillation, faecal fistula and gastrojejunal fistula.

Recurrence of jaundice after pancreatoduodenectomy for cancer of the pancreas

Recurrence of jaundice and/or cholangitis may be seen after pancreatoduodenectomy and may be due to small bowel obstruction. Nausea and vomiting are usually prominent features. The obstruction may be due to recurrent tumour or simply to adhesions. Laparotomy may be indicated to establish the diagnosis and to relieve the obstruction.

Postoperative chemoradiation for resectable cancer of the pancreas

Data from several randomized trials have shown a significant survival benefit in patients treated with infusional 5-fluorouracil (5FU) and external beam radiation following pancreatectomy. Therefore, in patients who are well enough to tolerate it, adjuvant chemoradiation is recommended. Newer agents such as gemcitabine are increasingly used in combination with radiation as an alternative to 5FU. Indeed the first line agent recommended by the National Institute of Health and Clinical Excellence is gemcitabine; other drugs used are 5FU and capecitabine.

Monitoring of recurrence

A small number of patients with resectable pancreatic cancer have elevated levels of tumour markers such as CA19-9, POA or CEA preoperatively. When this is the case, serial monitoring of either marker may be useful in confirming the completeness of surgical excision and in the detection of recurrent pancreatic cancer.

Replacement of pancreatic exocrine function

Adequate pancreatin tablets (Viokase, Pancrease, Creon) must be taken with each meal. The number of tablets must be increased if steatorrhoea develops. The patient is advised to take a low-fat, high-protein and carbohydrate diet in the form of frequent regular small meals. Patients must take acid-reducing agents (H_2-blockers) half an hour before taking the pancreatic enzymes to prevent acid inactivation.

Factors influencing prognosis after resection for ductal adenocarcinoma of the head of the pancreas

The mortality for major pancreatic resection is between 0% and 5% in specialized centres. Death as a result of operative complications usually occurs within the first 2 months of operation. After 2 months and up to 2 years, death is usually due to metastatic pancreatic cancer although a few individuals can present as late as the end of the third year with metastatic disease. If the patient has survived 3 years, the cause of death is usually unrelated to pancreatic cancer.

Four factors appear to determine survival after pancreatoduodenectomy.

- The site of origin of the cancer. Ampullary and distal bile duct tumours have a better prognosis than pancreatic cancer (Figure 27.24).
- The operative mortality and morbidity of the surgical team. It is well established that the operative mortality, morbidity and eventual survival of patients following this and other major operations are dependent on the experience and expertise available in the institution where the operation is performed (case load and expertise). Hospitals where a large volume of the operation is performed have much better overall results than those where the operation is performed occasionally.
- The stage of the tumour.
- The biological behaviour of the tumour.

Whether these last two factors are independent variables or are different manifestations of the same variable is debatable. It is generally agreed that a uniform staging system for pancreatic cancer is clearly desirable. However, a major problem in staging the disease is that it can only be performed retrospectively after an extensive pancreatoduodenal resection. The following parameters are considered important.

- The size of the tumour: lesions less than 2 cm in diameter have a higher resectability rate and the best overall survival. Lesions greater than 4 cm have the lowest resectability rate and the lowest overall survival. Caution must be expressed here concerning intraoperative decision-making based on size alone. It is not unusual for a small lesion to induce a substantial amount of surrounding pancreatitis and create a larger mass effect which impinges on neighbouring structures.
- Positive lymph nodes are an important negative prognostic factor. Hence, it is important to perform an adequate lymphadenectomy *en bloc* with the pancreatoduodenectomy specimen to ensure appropriate staging by the pathologists. How extensive the lymph node dissection and excision of surrounding soft tissues should be is debatable.
- Extrapancreatic invasion adversely affects survival. Since microscopic peripancreatic invasion appears to be important, the extent of the peripancreatic excision leading to skeletonization of the major vessels as advocated by several Japanese surgeons makes sense in order to provide a microscopically curative dissection. Whether a pylorus-preserving pancreatoduodenal resection can be achieved at the same time is debatable.
- Major vascular involvement: this is also an adverse prognostic factor. In most instances, this has the connotation of unresectability if the hepatic artery, coeliac axis or superior mesenteric artery is invaded. However, a short segment of portal vein–superior mesenteric vein axis is not necessarily incompatible with long survival, provided that *en bloc* excision of the adherent venous segment helps achieve a microscopically curative surgical resection.
- Histological grade of the tumour: poorly differentiated tumours are associated with lower survival than well-differentiated ones. Using absorption cytometry to measure DNA content of cells, patients with diploid cancers have a 50% 5 year survival compared with no 5 year survival among those patients with aneuploid cells.
- The amount of blood transfusion in the perioperative period. Just like in the case of colon cancer, this factor has been proposed as an independent variable affecting survival. Patients who underwent pancreatoduodenectomy with 2 units or less of blood transfusion have a median survival of 24.7 months, whereas those who required 3 units or more in the perioperative period survive only a median of 10.2 months.
- Perineural involvement. Extensive microscopic involvement of perineural lymphatics is usually associated with a poor prognosis, but such tumours are, by and large, extensive in terms of both peripancreatic involvement and nodal metastases.
- Sex of the patient: women appear to live longer than men after pancreatoduodenal resection for pancreatic cancer.

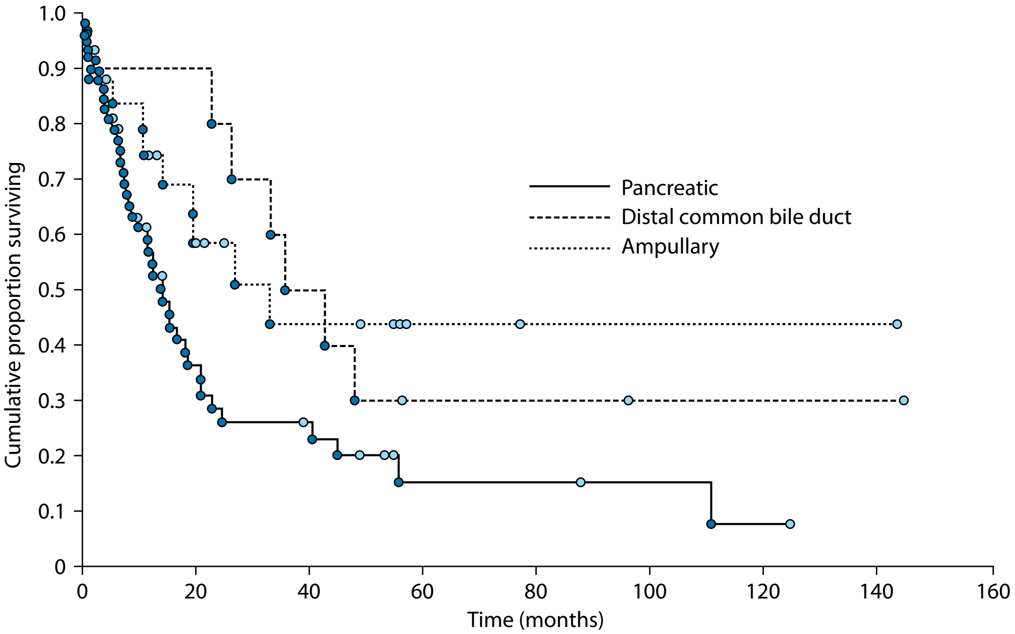

Figure 27.24 Different survival rates after resection of pancreatic cancers, cancers of the distal common bile duct and periampullary cancers.

Palliation of pancreatic cancer

The surgeon can palliate incurable pancreatic cancer in several ways.

- Relief of jaundice, pruritus and impending cholangitis: the biliary tract decompression can be done either by cholecystojejunostomy or by hepaticojejunostomy (each with a diverting enteroenterostomy), depending on whether the cystic duct is widely patent and is in full communication with the biliary tree proximal to the obstructing cancer.
- Relief of duodenal obstruction. If the patient lives for more than a few months, duodenal obstruction invariably occurs. It is therefore advisable to perform a gastrojejunostomy at the primary operation. More recently endoscopically inserted wall stents are used for established duodenal obstruction.
- Relief of pain. The coeliac plexus can be infiltrated with 50 mL of 50% alcohol or with 20 mL of 6% phenol. This may be helpful in patients with cancer of the body of pancreas when the pain is a prominent feature. Cordotomy, extensive sympathectomy and stereotactic thalamotomy have all been tried with minimal or no objective response. More recently, thoracoscopic splanchnicectomy has been shown to achieve substantial pain relief in inoperable pancreatic cancer.

All locally unresectable or metastatic masses must be biopsied until a definite histological diagnosis is made on frozen section histology. The main tumour mass must be outlined with silver clips to provide a possible radiation port. Postoperative chemoradiation for locally advanced, unresectable tumours is indicated. If liver metastasis or carcinomatosis is found at laparotomy, single agent chemotherapy with gemcitabine may provide palliation and improve the patient's quality of life.

When a patient is unfit for surgery, or refuses operation, an alternative method of palliating the obstructive jaundice is by endoscopic sphincterotomy and placement of biliary stent. This approach does not relieve any duodenal obstruction which may be present. If the patient survives for more than a few months, recurrent cholangitis associated with stent blockage is a problem that necessitates regular endoscopic removal and replacement of the stent. Newer self-expandable metallic devices such as the wall stents have improved patency rates, and are nowadays used in preference to plastic stents. Percutaneous transhepatic placement of an internal expandable metal stent inserted by the interventional radiologists is an alternative option for palliation of the jaundiced patient with malignant biliary obstruction.

Intraduct papillary mucinous neoplasms of the pancreas

Mucinous tumours of the pancreas include serous cystic lesions, mucinous cystic neoplasms, solid pseudopapillary neoplasms, cystic islet cell tumours and intraductal papillary mucinous neoplasms of the pancreas (IPMNs). Although sometimes referred to as mucinous duct ectasia or intraductal papillary mucinous tumours, the term IPMNs or IPMTs is generally used. These tumours are composed of mucin-producing columnar cells with papillary proliferation and cyst formation and may involve the main pancreatic duct, the branch ducts, or both. First described in Japan in 1982 in a small series of patients with dilated main pancreatic ducts, patulous ampullary orifices and mucus secretion from the pancreatic duct, they were thought to be rare tumours, but their incidence has increased markedly during the last decade, mainly due to increased diagnosis by advances in medical imaging. The distinction between IPMN and mucinous cystic neoplasm (MCN) was not established before 1999, and it is now thought that many lesions previously classified as MCNs were in fact IPMNs.

Pathology

IPMNs are primarily intraduct tumours with a papillomatous growth pattern, which is associated with excessive mucin secretion and results in progressive ductal dilatation or cyst formation. IPMNs occur in four forms: (1) segmental involvement of the main pancreatic duct, (2) diffuse involvement of the main pancreatic duct, (3) macrocystic involvement of a branch duct and (4) microcystic involvement of a branch duct. The correct diagnosis, previously only possible with ERCP, can now be made with CT and MRI-MRCP.

Pathologically, IPMNs can be divided into the three categories according to the criteria established by the World Health Organization. These are:

- IPMN adenoma
- IPMN borderline
- intraductal papillary mucinous carcinoma.

Intraductal papillary mucinous carcinoma is further categorized into non-invasive (carcinoma *in situ*) and invasive carcinoma. The prevalence of malignant lesions associated with IPMN, including carcinoma *in situ* and invasive carcinoma, is variously reported to range widely between 30% and 88%. IPMNs represent a spectrum of neoplasms with varying aggressive behaviour from small benign adenomas to aggressive invasive cancer. Although IPMNs carry a relatively more favourable prognosis than ductal adenocarcinoma of the pancreas, these lesions are established precursors to invasive adenocarcinoma of the pancreas. The preoperative determination of the benign or malignant type of IPMN in the individual patient dictates the surgical treatment and determines the prognosis. The features indicative of malignancy include:

- marked dilatation of the main pancreatic duct (in some but not all studies)
- main duct type or combined type lesions
- large mural nodules
- solid mass
- diffuse or multifocal involvement
- large tumours of the branch duct type (in some but not all studies)
- widely opened orifice of the papilla of Vater on ERCP.

Clinical features

The true incidence of IPMNs is not known. However, it is thought that IPMNs account for 1–3% of neoplasms of the exocrine pancreas and 20–50% of cystic pancreatic neoplasms. These tumours are usually diagnosed in the elderly (fifth to sixth decade) with a male-to-female ratio for main duct IPMNs of 1.1 to 3:1, and 0.7 to 1.8 for branch duct IPMN. However, the sex ratio varies geographically, with a male predominance in Japan and Korea and a more even distribution in Western countries.

Clinical features suggestive of malignancy include a recent onset or worsening of diabetes, steatorrhoea and jaundice. In contrast, patients with benign IPMNs present more commonly with abdominal pain and a longer duration of the symptoms.

Surgical treatment

Case selection for surgical treatment vs surveillance depends on the assessment of the lesion by ERCP and other imaging tests, and the patient's age and fitness for surgery. Features indicative of malignancy (outlined in the previous section) are indications for surgical resection in all fit patients, irrespective of age. Expectant policy with surveillance is indicated in asymptomatic patients with branch IPMNs, absence of any features (clinical or radiological) of malignancy and those at high operative risk because of comorbid disease.

As large duct IPMN affects the head of the pancreas and the uncinate process (60%) and less commonly the entire gland, the recommended treatment is pancreaticoduodenectomy for proximal disease (with frozen section clear resection margins) and total pancreatectomy. All patients with dilatation of the entire ductal system of the gland require total pancreatectomy. IPMNs involving only a segment of the pancreas (branch duct disease) present problems in adequate complete clearance. In these cases, intraoperative frozen section histology for establishing tumour-free resection margins is mandatory. The surgeon must continue the resection until negative margins are obtained. Even so, negative resection margins carry a reported local recurrence rate of from 0% to 25% depending on the length of follow-up.

Lesions of the endocrine pancreas

Pancreatic islet cells are components of the gastroenteropancreatic part of the diffuse neuroendocrine system. Cells belonging to this system are commonly referred to as APUD cells because they share the following cytochemical characteristics: a high amine content (A); the capacity for amine precursor uptake (PU); and the property of decarboxylation (D) of these precursors to form amines. Tumours arising from the APUD series of cells are called APUDomas. Although Pearse originally suggested that all APUD cells were probably derived from neural crest cells, it is now generally recognized that the gastroenteropancreatic APUD cells (including pancreatic islet cells) probably arise from endoderm (dedifferentiation theory). Regardless of their origin, the APUD cells share similarities in structure, properties and potential. All have characteristic histological, histochemical, immunocytochemical and electron microscopic appearances and all contain the enzyme neurone-specific enolase that is the universal marker for such cells and their hyperplastic and neoplastic lesions.

APUD cells are capable of synthesizing and secreting a great variety of peptides which exert regulatory effects by four main modes of action:

- endocrine, i.e. involving secretion into the circulation to affect distant target sites
- paracrine, i.e. involving local secretion to act on adjacent cells
- neurocrine, i.e. involving secretion at neuronal synapses to act as a neurotransmitter
- neuroendocrine, i.e. involving release of a peptide product of the neurone into the circulation to act on other tissues.

Clinical syndromes may develop as a result of either inadequate or excessive production/release of the potent chemical messengers (e.g. inadequate insulin causing diabetes mellitus and excessive insulin leading to hypoglycaemia). The development of radioimmunoassays for a number of the gastroenteropancreatic peptide hormones has led to the understanding that hyperplastic as well as neoplastic pancreatic islet cells are capable of producing recognizable syndromes of hormone excess. Pancreatic tumours of the islet cell type may in fact secrete two or more identifiable peptide hormones although the threshold for the appearance of their respective clinical symptoms varies greatly and elevated levels of one hormone may be compensated by regulatory hypersecretion of other hormones. Endocrine tumours of the pancreas can be referred to as entopic if they produce hormones normally secreted by the pancreas (e.g. insulinoma, glucagonoma) and ectopic if they produce non-pancreatic hormones (e.g. gastrinoma, VIPoma). There is little correlation between tumour size and plasma hormone concentration or severity of clinical symptoms. Some 10–25% of patients harbouring pancreatic APUD tumours will have the multiple endocrine neoplasia type 1 (MEN-1) syndrome. The clinical syndromes associated with overproduction of identified pancreatic islet cell peptides are shown in Table 27.6.

The overwhelming majority and perhaps all islet cells additionally cosynthesize and cosecrete the protein chromogranin along with their peptide products. Elevated plasma levels of chromogranin or neurone-specific enolase are useful markers for pancreatic endocrine tumours and the MEN syndromes even in the absence of clinical symptoms or demonstrable hormonal excess. Immunohistochemical staining for these proteins confirms the endocrine nature of otherwise obscure pancreatic tumours.

With the exception of insulinoma, most endocrine pancreatic tumours are frankly malignant or at least have a high potential for metastatic spread. Compared with their non-endocrine pancreatic counterparts, the endocrine cancers are relatively slow growing and many apparently metastasize only to regional lymph nodes. This characteristic allows curative surgical therapy in a sizeable proportion of patients.

Historically, the symptoms, morbidity and mortality of the pancreatic endocrine tumour have been due primarily to hormonal hypersecretion but earlier detection and more effective treatment now can often minimize symptoms and forestall death until the advanced stages of malignant spread.

Overview of pancreatic endocrine tumours

Pancreatic endocrine tumours comprise a heterogeneous group of tumours of varying histological differentiation which are broadly divisible into (1) functioning and (2) non-functioning types. With *functioning tumours* the clinical symptom manifestations are the result of persistent autonomous hypersecretion of peptide/hormone(s). In contrast, *non-functioning tumours*, although capable of secreting various hormones (PP, human chorionic gonadotrophin, calcitonin, neurotensin, etc.), do not usually produce specific clinical symptoms resulting directly from overproduction of hormone(s). In this respect they are considered as *non-functioning* and do not produce specific recognizable syndromes. Some functioning tumours are rare and may also originate in non-pancreatic tissues (extrapancreatic), e.g. VIPomas, somatostatinoma, GRFoma, etc.

Epidemiology of pancreatic endocrine tumours and rare functioning tumours

The incidence of clinically detected pancreatic endocrine tumours is reported as 4–12 cases per million individuals. The commonest functioning pancreatic endocrine tumours are insulinomas (17%), followed by gastrinoma (15%). Collectively the others are classed as rare functioning tumours (RFTs) and include VIPoma (2%), glucagonoma (1%), carcinoid (1%) and somatostatinoma (1%). The majority of RFTs are well-differentiated and most are malignant (WHO group 2) and have usually metastasized to the liver by the time of diagnosis. The 5 year survival for localized disease is however good (variously reported at 60–100%). The survival drops to 40% in patients with regional disease and to 30% in patients with distant metastases.

RFTs which represent less than 10% of all pancreatic endocrine tumours can occur at any age but their average age at diagnosis is 50–55 years. They have an equal sex distribution. Some 25% of patients with pancreatic endocrine tumours have MEN-1 and these patients may develop multiple tumours either synchronously or subsequently (metachronous lesions). In contrast to the more common pancreatic endocrine tumours, the incidence of MEN-1 in patients with RFTs is much lower, i.e. about 2% for VIPomas and glucagonomas.

Detection and localization

The standard imaging procedures for pancreatic endocrine tumours and RFTs include EUS, contrast-enhanced helical CT or MRI of the abdomen in combination with somatostatin receptor scintigraphy (SRS). EUS is of proven efficacy in detecting most pancreatic endocrine tumours and can be combined with EUS-FNA, but is not generally available. SRS is considered a routine investigation for both primary tumours and metastases and should always be performed prior to surgery. Gallium-labelled somatostatin analogue PET can detect small tumours. Recently, reports of PET with 5-HTP or ^{18}F-DOPA have shown promising results in the detection of small well-differentiated tumours.

The laboratory tests for the detection of pancreatic endocrine tumours and RFTs include both specific [insulin, VIP, glucagon, somatostatin, GRF, adrenocorticotrophin hormone (ACTH)] and general (chromogranin A and PP) markers.

Pathology and genetics

Pathological diagnosis is obtained by biopsy and is performed using both haematoxylin and eosin staining and immunohistochemical staining with chromogranin and synaptophysin. The biological aggressiveness of the tumour is determined by the mitotic index obtained by counting 10 high-power fields and by calculation of the Ki-67 index. Genetic testing is indicated in cases of suspected familial predisposition to MEN-1 and in patients with other associated endocrinopathies, e.g. elevated serum calcium (hyperparathyroidism) or parathyroid hormone (prolactinoma).

Surgical treatment

In all patients with functioning tumours, specific measures to avoid hormonal crisis during surgery are essential. These include perioperative somatostatin analogue therapy and special anaesthetic measures. Curative surgery should be attempted even in the presence of localized metastatic disease to the liver. The primary pancreatic tumour is resected but the operation varies from pancreaticoduodenectomy (for large proximal tumours), enucleation (for small tumours of the head) and distal pancreatectomy with or without splenic preservation (for tumours of the distal pancreas). If malignancy is suspected, it should be confirmed by frozen section and the tumour resected with complete regional lymph node clearance. Complete resection of liver metastases should always be considered for both functioning and non-functioning tumours. Intraoperative contact ultrasound is helpful both in the detection and for guiding the anatomical resection of liver metastases. Hepatic resection may be done at the time of excision of the primary or subsequently depending on expertise and extent of hepatic resection necessary.

Palliative surgery (debulking of primary or metastases) may be indicated following case conference with the oncologist, as extensive debulking can control symptoms related to hormonal hypersecretion and improves the efficacy of chemotherapy. Bilateral adrenalectomy is indicated in patients with excess ACTH secretion resulting in Cushing syndrome. Liver transplantation may be indicated for a small subset of patients with diffuse liver disease without extrahepatic metastases in whom life-threatening hormonal symptoms persist despite medical therapy.

Embolization and other methods of local ablation

Selective embolization alone or in combination with intra-arterial chemotherapy (chemoembolization with streptozotocin + doxorubicin or mitomycin C) is an established procedure which is effective in controlling symptoms and retarding progression of tumour and yields good control of symptoms and partial tumour response in 50%. Chemoembolization carries a low mortality rate but is accompanied by significant morbidity due to hepatic or renal failure. In addition, patients often develop the postembolization syndrome consisting of prolonged fever, right upper quadrant pain, nausea, elevation of liver enzymes and a decrease in albumin and prothrombin time. The syndrome is treated with adequate analgesia and hydration together with infusion of somatostatin analogues.

Other local ablative methods, which may be used alone or in combination with surgery include radiofrequency ablation, cryotherapy and laser thermal ablation but these are only effective for limited disease with deposits not exceeding 4–5 cm in diameter.

Medical therapy

Both somatostatin analogues and interferon are effective in the control of symptoms caused by functioning PETs, and this also includes RFTs. Thus somatostatin therapy results in dramatic improvement in 80–90% of patients with VIPoma (control of the diarrhoea) and in patients with glucagonoma (subsidence/minimization of rash) and 60–80% exhibit a reduction in VIP and glucagon levels. However, symptomatic relief is not always accompanied by a reduction in circulating hormone levels, indicating that somatostatin analogues have direct effects on the peripheral target organ. Recurrence of symptoms is encountered frequently. It may respond to an increase in dose of somatostatin analogues but this is usually a temporary measure. Although the antitumour efficacy of somatostatin analogues is low with objective tumour responses of >10%, disease stabilization of up to 40% has been reported especially in subgroups of patients with slowly progressive well-differentiated tumours expressing sst2 receptor subtype (i.e. with a positive SRS). Somatostatin analogue therapy is initiated with short-acting substance (octreotide 100 μg subcutaneously two or three times daily) for 1–2 days with titration according to clinical response. Treatment is then changed to slow-release lanreotide SR i.m., lanreotide autogel s.c. or sandostatin–LAR (long-acting release) i.m. (every 4 weeks). Interferon is indicated in metastatic slow-proliferating tumours and can be effective in VIPomas not responding to somatostatin analogues.

Systemic chemotherapy is indicated in patients with metastatic and progressive disease using combinations of streptozotocin and 5FU and/or doxorubicin with objective response rates averaging 35%. Peptide receptor radionuclide therapy (PRRT) was introduced with the development of chelators suitable for radiometal labelling allowing for coupling of modified somatostatin analogues with trivalent metal ions (indium, gallium, yttrium, lutetium, etc.). The efficacy of PRRT in the treatment of advanced PETs with positive SRS has been demonstrated, although the reported data for RTTs are limited.

Follow-up

The follow-up of PETs and RFTs should include clinical, biological and imaging tests at regular intervals with most patients being assessed at intervals of 3–6 months.

Hyperinsulinism

Hyperinsulinism in its primary form embraces several different varieties of pancreatic islet cell disease which include -cell hyperplasia/microadenomatosis and -cell neoplasia (insulinoma). These conditions manifest as symptomatic hypoglycaemia. Insulinomas are the most common of pancreatic APUDomas (75% of symptomatic cases) and the most frequent cause of organic primary hyperinsulinism. In the adult, approximately 80% of insulinomas are benign solitary tumours. There is an even distribution of tumours in the head, body and tail of the pancreas. Multiple tumours are usually present in patients with MEN-1 syndrome and are found in about 10% of cases. -cell carcinoma occurs in 5–10% and is characterized by local invasion and metastatic spread to regional lymph nodes and liver. Primary hyperinsulinism is rare in infants and children but, when encountered, a form of -cell hyperplasia (nesidioblastosis) is seen much more frequently than neoplasia. In contrast, microadenomatosis or islet cell hyperplasia is only very rarely found in adults.

Clinical features and diagnosis of hyperinsulinism

Hypoglycaemia induces a constellation of symptoms reflecting activation of the autonomic nervous system and release of epinephrine (adrenaline) together with cerebral dysfunction related to insufficient glucose oxidation to meet energy needs. The symptoms of adrenergic hyperactivity are more apt to occur with rapid falls of plasma glucose and include weakness, sweating, hunger, palpitations and tremulousness. Neuroglycopenia manifests as headache, visual disturbance, dizziness and confusion and may progress to abnormal behaviour, seizures and coma. Hypoglycaemic episodes are often misinterpreted as suggesting brain tumour, epilepsy, alcoholism or drug abuse, psychosis or even hysteria. Delays in diagnosis and treatment of hypoglycaemia are common and contribute to the morbidity and mortality of the condition. The most important clue to early correct diagnosis is the relationship of the symptoms to periods of food deprivation or physical exercise and the relief of symptoms following food ingestion. In cases where diagnosis is long delayed, patients often develop obesity from increased carbohydrate intake as a behavioural adaptation to repeated episodes of symptomatic hypoglycaemia. Thus, it is not surprising that the diagnosis of hyperinsulism is often delayed for several years following the onset of symptoms. Patients are often ‘shunted’ from neurologist to cardiologist to psychiatrist.

Differential diagnosis of hypoglycaemia

Hypoglycaemia may occur in the fasting state or may be postprandial (reactive) in nature. In the latter condition, low plasma glucose concentrations occur only in response to meals. In fasting hypoglycaemia, a period of hours to a few days is required to precipitate hypoglycaemia. While patients with fasting hypoglycaemia (particularly insulinomas) may also exhibit a reactive component, patients with reactive hypoglycaemia never have symptoms when food is withdrawn. Fasting hypoglycaemia usually indicates a specific underlying disease process while symptoms suggestive of postprandial hypoglycaemia are often found in the absence of an identifiable organic lesion.

Postprandial (reactive) hypoglycaemia

The more common causes of postprandial hypoglycaemia are:

- alimentary hyperinsulinism
- hereditary fructose intolerance
- galactosaemia
- leucine sensitivity
- idiopathic
  - true hypoglycaemia
  - non-hypoglycaemia.

Alimentary hypoglycaemia is the most common type seen clinically and is usually found in patients who have undergone gastrectomy, pyloroplasty, gastrojejunostomy or, rarely, proximal gastric vagotomy. Symptoms occur within a few hours postprandially and are particularly prominent after meals of high carbohydrate content in the form of mono- and disaccharides. Although the exact pathophysiological mechanisms remain to be defined, it is clear that rapid gastric emptying of simple sugars by the postoperative stomach with brisk absorption of glucose and excessive insulin release are of central importance. The attacks can be provoked in affected individuals by oral ingestion of 100 g of glucose in water. A rapid abnormal rise in plasma glucose together with a parallel, and often exaggerated, plasma insulin response occur following glucose challenge. Hypoglycaemic symptoms appear within 1–2 hours as the insulin response and/or effect exceeds the requirement of euglycaemia. True alimentary hypoglycaemia may occur in the absence of gastrointestinal surgery but is rare.

Reactive hypoglycaemia is often misused as a diagnostic label in patients suffering from anxiety states rather than true idiopathic reactive hypoglycaemia. Although some of these individuals manifest a very mild and asymptomatic depression in plasma glucose during the 5 hour glucose tolerance test, hypoglycaemia cannot be documented after normal meals containing less than 100 g of rapidly absorbable carbohydrate. This is in contrast to the occasional case of true idiopathic reactive hypoglycaemia where spontaneous symptomatic episodes are reproducible and accompanied by demonstrably low plasma glucose levels. Most patients without true hypoglycaemia have postprandial adrenergic discharge as a result of underlying anxiety and stress. The epinephrine (adrenaline)-mediated symptoms suggest hypoglycaemia but occur in its absence and are presumably psychogenic in origin.

Fasting hypoglycaemia

The major causes of fasting hypoglycaemia are:

- conditions primarily due to underproduction of glucose
  - hormone deficiencies: hypopituitarism, adrenal insufficiency, catecholamine deficiency, glucagon deficiency
  - enzyme defects: glucose-6-phosphatase, liver phosphorylase, pyruvate carboxlase, PEP (phosphoenolpyruvate)-carboxykinase, fructose-1, 6-diphosphatase, glycogen synthetase
  - substrate deficiency: ketotic hypoglycaemia of infancy, severe malnutrition, muscle wasting, late pregnancy
  - acquired liver disease: hepatic congestion, severe hepatitis, cirrhosis
  - drugs: alcohol, propranolol, salicylates
- conditions primarily due to overutilization of glucose
  - hyperinsulinism: insulinoma, exogenous insulin, sulfonylureas, immune disease with insulin antibodies
  - appropriate insulin levels: extrapancreatic tumours, cachexia with fat depletion, carnitine deficiency, carnitine acyltransferase deficiency.

In this condition one or both of the following mechanisms may be operative: (1) hepatic glucose production is not adequate to meet ordinary tissue demands; (2) peripheral glucose utilization is increased to such a degree that maximal hepatic production is insufficient to match glucose egress from the plasma component. Since hepatic glucose output in normal fasting man is between 100 and 200 g per day, a requirement for greater than 200 g of intravenous glucose over a 24 hour period to prevent hypoglycaemia can be taken as evidence for overutilization of glucose.

From the practical standpoint, fasting hypoglycaemia in an otherwise healthy individual is always due to hyperinsulinism that is attributable to an insulinoma in the adult or islet cell hyperplasia in the neonate or infant. Although patients with hyperinsulinism classically describe or manifest symptoms under fasting conditions in the early morning hours before breakfast or in the late afternoon following exertion, attacks may be highly unpredictable and distributed randomly throughout the day. While it is obvious that the development of fasting hypoglycaemia in insulinoma patients is due to excessive insulin secretion, the hypoglycaemia may result from insulin-mediated suppression of hepatic glucose production as well as augmentation of glucose utilization. Most patients learn quickly that symptoms can be relieved by intake of food or sweetened drinks. Accordingly, a proportion of patients gain substantial amounts of weight.

In 1935, Whipple and Franz reviewed 35 cases of insulinoma and enunciated the primary diagnostic criteria which became known as Whipple's triad:

- hypoglycaemic symptoms are produced by fasting
- hypoglycaemia is documented during symptomatic episodes (blood glucose level below 50 mg/dL)
- symptoms are relieved by glucose intake.

While the presence of Whipple's triad strongly suggests the presence of an insulinoma, differentiation from other causes of fasting hypoglycaemia is crucial. Factitious hypoglycaemia due to surreptitious self-administration of insulin must always be considered in cases posing diagnostic difficulty. Currently, the diagnosis of insulinoma is based upon three elements:

- recognition of the probable nature of the patient's symptoms
- presence of Whipple's triad
- demonstration that the plasma insulin concentration is inappropriately high for the existing level of plasma glucose.

Thus, it is not the absolute level of insulin but its concentration relative to the plasma glucose that is diagnostic. Although absolute elevation of the insulin level is present in many insulinoma patients, rapid degradation of insulin by the liver is probably responsible for the normal absolute levels seen in others with functioning islet cell tumours. For this reason, the ratio of plasma immunoreactive insulin to plasma glucose is considered of greater diagnostic accuracy than absolute levels of insulin and glucose. An insulin (μg/mL) to glucose (mg/dL) ratio of greater than 0.3 indicates insulinoma. It is therefore essential in the investigation of suspected or documented hypoglycaemia to measure simultaneous insulin and glucose levels from the same plasma sample obtained at the time of hypoglycaemia.

Virtually all insulinoma patients will develop symptomatic hypoglycaemia during a diagnostic 72 hour fast. About 90% will manifest symptoms within 48 hours, 80% within 24 hours and 40% within 2 hours of fasting. The plasma glucose level at the time of symptoms is almost invariably less than 40 mg/dL (2.2 mmol/L). In normal individuals the level of immunoreactive insulin during fasting is very low to almost undetectable. At the time of fasting hypoglycaemia, almost all insulinoma patients have basal insulin levels greater than 5 μg/mL. Other causes of fasting hypoglycaemia such as fibrosarcoma and other non-pancreatic tumours, glucocorticoid deficiency or diffuse liver disease may exhibit a positive Whipple's triad but in none will the associated immunoreactive insulin level be increased.

Plasma proinsulin levels are also helpful in the diagnosis of insulinoma. Proinsulin is the single chain precursor of insulin and is normally present to an extent of 20% or less of the total immunoreactive insulin. Under ordinary circumstances, proinsulin is split into C-peptide (connecting chain) and insulin prior to storage in β-cell granules, with only a small percentage being secreted into the portal venous circulation (Figure 27.25).

Because insulinoma tumour cells are usually less differentiated than normal β-cells, they secrete more proinsulin. Simple determination of proinsulin in overnight fasted plasma provides good separation of patients with islet cell tumour from normal individuals in 90% of cases. Proinsulin can be expressed as the absolute level or as a percentage relative to total insulin concentration in plasma. Occasionally, some well-differentiated insulinomas may have normal proinsulin secretion. Greatly elevated values (greater than 50% of total immunoreactive insulin) are often associated with malignant tumours.

Provocative tests in the diagnosis of insulinoma

While no other test is as simple, safe and accurate as prolonged fasting with measurement of glucose and insulin, on rare occasions provocative testing may be needed. A variety of such tests have been advocated and all can be misleading and some potentially dangerous. The glucose tolerance test and the leucine infusion test are mentioned only to be condemned because of their inaccuracy. None of the others is diagnostic in more than 70% of cases. Their further disadvantage is the provocation of occasionally severe hypoglycaemic reactions resulting from release of substantial amounts of insulin from the tumour.

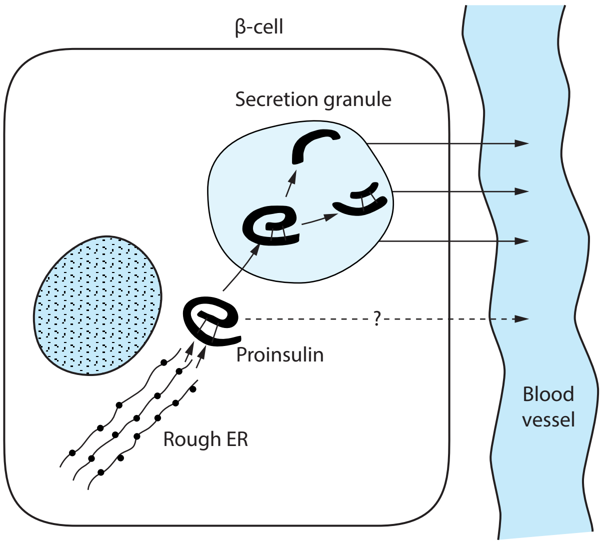

Figure 27.25 Conversion of proinsulin to insulin and C-peptide within the pancreatic β-cell. Equimolar amounts of insulin and C-peptide are liberated during exocytosis. ER signifies endoplasmic reticulum. In normal circumstances only small amounts of the precursor, proinsulin, are released into the bloodstream, while insulinomas release proinsulin into the circulation in larger amounts.

The calcium infusion test has been used as a provocative test for a number of APUDomas, including gastrinoma, medullary thyroid carcinoma and carcinoid tumours as well as insulinomas. Patients with insulinomas release insulin and proinsulin with resultant hypoglycaemia after calcium infusion. In order to avert the hypoglycaemic attack attending calcium infusion-stimulated insulin release, a combined glucose–calcium infusion has been devised in which insulin release after glucose alone and after glucose plus calcium is compared. This, like all stimulation tests, suffers from a relatively low diagnostic accuracy and is indicated only when diagnostic difficulties arise.

The tolbutamide and glucagon tolerance tests are performed by intravenous administration of the respective drug followed by plasma collections for glucose and insulin determinations over a 1 hour period. In the tolbutamide test, a plasma insulin level of 195 μg/mL or greater is considered diagnostic. The critical insulin value in the glucagon test is 160 μg/mL.

A useful suppression test involves infusion of fish insulin to produce hypoglycaemia. While normal subjects respond with suppression of endogenous insulin secretion, patients with insulinoma fail to suppress because of the autonomous nature of hormone release by the tumour cells. Porcine insulin may be used instead of fish insulin but C-peptide must then be measured as a marker of endogenous insulin release. While the non-suppressibility of endocrine tumours is often interpreted as a sign of malignancy, caution in this regard should be exercised with respect to insulinomas where a different degree of suppressibility reflects a different degree of functional dedifferentiation but not necessarily malignancy.

Newer tests for insulinoma which may have good diagnostic accuracy without danger of hypoglycaemia are the sequential suppression tests using somatostatin followed by diazoxide with measurement of insulin levels and glucose consumption and the computer-controlled glucose infusion system which measures the glucose infusion rate required to maintain plasma glucose constant at 80 mg/dL (4.4 μmol/L).

Factitious hypoglycaemia must always be considered and this is especially true in individuals having access to insulin or oral hypoglycaemic agents. Concomitant measurement of plasma levels of C-peptide is critical in such circumstances as insulin and C-peptide are secreted in equimolar amounts by both the normal β-cells and the insulinoma cells. The C-peptide level thus serves as a direct marker of endogenous insulin release. Since all of the diagnostic tests presented can be positive following administration of exogenous insulin, the finding of an inappropriately depressed level of C-peptide can readily identify the surreptitious insulin user.

Preoperative tumour localization

There are some who doubt the value of preoperative imaging of insulinomas as the overall accuracy of preoperative localization tests is low especially for small tumours (<1.0 cm) and averages

30–35% overall including ultrasonography, CT and MRI. Invasive tests [angiography, transhepatic portal venous sampling (THPVS), EUS] can localize lesions in >70%. In contrast, intraoperative inspection and palpation gives superior localization (90%) and this is improved by contact intraoperative ultrasound (93–95%), especially in insulinomas not detected by preoperative imaging (occult insulinomas). Most insulinomas are small benign adenomas with over 75% being less than 1.5 cm in diameter.

The counter argument to this view is that insulinomas may be wholly embedded in the pancreas and not visible on its exposed surface. Moreover, they may be difficult to distinguish by palpation from a normal lobule of pancreas or a peripancreatic lymph node and many centres do not have experience in or access to intraoperative ultrasound. For these reasons, an attempt at preoperative localization is still considered good practice, if not mandatory once the definite diagnosis of hyperinsulinism has been made.

Angiography remains a reliable method of delineating insulinomas. The use of superselective injection of contrast with subtraction technique and magnification allows confident identification of tumour 'blush' due to the hypervascularity. Care must be exercised to avoid false-positive localization related to the presence of accessory spleens, large peripancreatic lymph nodes and hypervascular segments of normal pancreas. The calcium arteriogram appears to be the most sensitive test. Feeding pancreatic arteries are selectively catheterized. Calcium stimulates insulin release. A catheter positioned in the hepatic vein is used to measure insulin levels 30–60 seconds following calcium injections. This permits a regional localization.

Recent improvements in imaging technology have enabled increasing detection rates as high as 70% for CT, 80% for MRI and 90% for EUS. Rapid sequence angio-CT allows improved definition of small slightly hypervascular tumours relative to normal pancreas. In general, however, lesions less than about 7–8 mm are poorly detected by currently available imaging tests.

Octreoscan is a non-invasive test in which intravenously injected octreotide, labelled with radioactive tracer, binds to tumours with somatostatin receptors. The sensitivity is related to expression of a special subset of somatostatin receptors. In contrast to other neuroendocrine tumours, insulinomas do not express significant amounts of the subtype 2 (sstr2) somatostatin receptor and for this reason it does not have an established role in the preoperative localization of insulinomas in view of its low yield.

EUS is the latest modality used to detect pancreatic tumours and can identify lesions as small as 2–3 mm. The sensitivity for EUS ranges from 80% to >90% for the detection of insulinomas, but it is a highly observer-dependent technique that demands special expertise.

In spite of their great utility in the localization of these small tumours, the results of imaging tests cannot be interpreted as definitive information. When a solitary adenoma is defined, the surgeon must remember that a second tumour not seen may still be present. Likewise, when several tumours are defined, the probability of additional lesions not seen is very real. Hence, positive preoperative localization studies in no way remove the surgeon's obligation to carry out a complete exploration of the entire pancreas preferably aided by intraoperative contact ultrasound scanning of the entire gland.

When imaging techniques fail to identify the lesion, measurement of immunoreactive insulin in blood sampled from selective catheterization of small pancreatic veins via the percutaneous transhepatic route is indicated. This technique is known as THPVS and is reported to correctly localize tumours not detected by other tests. At the time of portal sampling, samples are also drawn from the hepatic veins to detect metastatic or rare primary sources from within the liver. In addition, arterial samples are drawn periodically to detect any potentially confusing variations in systemic concentrations. THPVS is not without risks and should be confined to centres with very experienced angiographers and to patients who are candidates for abdominal re-exploration following an unsuccessful prior operation.

Surgical management

Without positive preoperative localization of a suspected insulinoma, the surgeon must be totally convinced that the diagnosis is correct before embarking on an operative search. However, with sufficiently strong biochemical evidence supporting the presence of an insulinoma, exploratory surgery is always indicated unless the patient cannot withstand the procedure. The entire pancreas and peripancreatic area must be examined visually and by palpation at operation. This requires access, exposure, assistance and gentle technique. Full mobilization of the gland should always be performed so that careful palpation between thumb and fingers is possible. Intraoperative contact ultrasonography has proved to be of great value in finding small, deeply situated tumours (Figure 27.26).

Solitary insulinomas should be enucleated whenever possible as a good cleavage plane is usually easily established between tumour and adjacent normal pancreas. Care must be taken to avoid injury to the pancreatic duct. Since the great majority of insulinomas are solitary and benign, distal pancreatectomy or, very occasionally, a Whipple type pancreaticoduodenectomy with pyloric preservation is justified for deeply situated tumours that cannot be safely enucleated. Very rarely is a Whipple operation justified for multiple tumours in the head of the pancreas since the likelihood of occult additional tumours being present in the body and tail of the gland is very substantial. Subtotal distal resection for multiple tumours throughout the gland, as seen in MEN-1 patients, is appropriate.

When malignant disease is encountered which can be extirpated by total pancreatectomy and regional lymphadenectomy, this should be done. Even if the tumour is inoperable, as much tumour mass is removed as is safely possible since debulking may provide good palliation with resolution of hypoglycaemic symptoms and increased efficiency of chemotherapy.

With a negative exploration, management options depend upon the clinical situation and the informed consent obtained preoperatively. If not contraindicated by these considerations, it is appropriate to perform pancreatectomy distal to the superior mesenteric vessels. If immediate examination of the thinly sliced resected specimen reveals no tumour and the patient's blood glucose exhibits no rise within 1 hour, it may be elected to

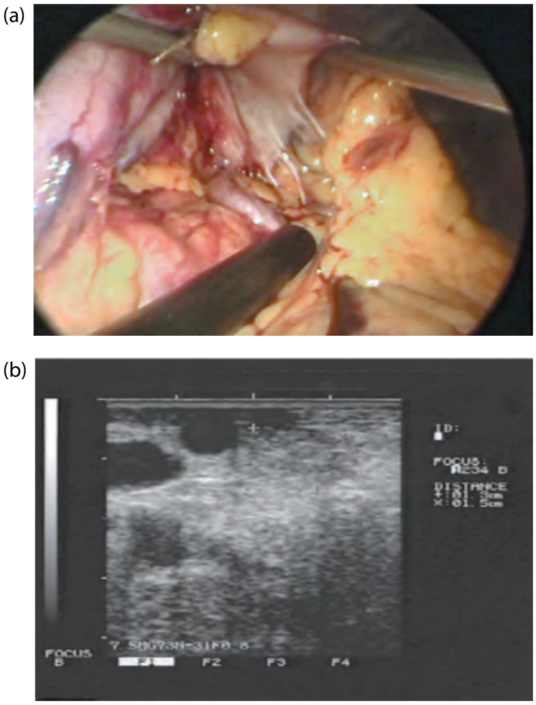

Figure 27.26 Laparoscopic contact ultrasonography of the pancreas after complete exposure of the gland in a patient with an 'occult' 6 mm insulinoma (seen between crosses) and lying close to the splenic vein. To palpation, insulinomas characteristically are slightly firmer than normal pancreas. Enlarged lymph nodes in the peripancreatic region and any liver lesions found should be submitted for frozen section histological evaluation to exclude metastatic disease. Histological examination of primary endocrine lesions in the pancreas is unreliable in the detection of malignancy unless obvious perineural or vascular invasion is present.

perform 90% or even total pancreatectomy. Arguments in favour of the lesser procedure include:

- a small tumour may be overlooked and subsequently found in the resected specimen
- symptoms of hypoglycaemia can be controlled by this procedure alone (in the absence of tumour resection) in 20% of cases
- diazoxide therapy is often successful in controlling symptoms in those uncontrolled by the operation
- the procedure usually does not cause permanent diabetes mellitus.

The benefits of blind total pancreatectomy include:

- removal of an occult lesion that could be an early malignancy
- elimination of the possible need for re-exploration that is difficult and hazardous
- omission of drug therapy for prolonged periods with its undesirable side effects.

It should be mentioned that patients not evaluated preoperatively with percutaneous THPVS for insulin levels perhaps should be referred to a specialized centre for this test and then a second, more directed operation performed. Blind Whipple operations are likewise not recommended.

The results of surgical treatment of insulinoma suggest that about 75% of patients are cured with some 10% developing diabetes following extensive pancreatic resection. About 10–15% of patients have persistent or recurrent hypoglycaemia requiring reoperation at some time. The overall surgical mortality is between 0% and 10% and is related to the extent of resection and expertise of the surgeon. The major operative complications are pancreatitis, abscess, fistula and pseudocyst formation.

Neonatal and infantile hyperinsulinism

Excessive insulin secretion accounts for 20–30% of all cases of unremitting hypoglycaemia in neonates and infants. Such hypoglycaemia can lead to irreversible central nervous system damage and thus requires early recognition, thorough investigation and expeditious treatment. A high intravenous and/or oral glucose intake is mandatory. Additional treatment with diazoxide, somatostatin or a variety of other agents [epinephrine (adrenaline), diphenylhydantoin, glucocorticoids, glucagon, growth hormone] is often required. When hypoglycaemia due to documented hyperinsulinaemia cannot be adequately controlled with medical therapy, urgent operation must be undertaken. Since the overwhelming majority of neonates and infants with hyperinsulinism have nesidioblastosis (-cell adenomatosis or islet cell hyperplasia) as the cause, imaging techniques such as arteriography, ultrasonography and CT have no place in the evaluation of these cases. Likewise, palpation of the pancreas at operation and biopsies for frozen section histological examination are non-contributory. The appropriate procedure is 80–90% extended distal pancreatectomy with splenic preservation. If careful postoperative monitoring of glucose levels indicates inadequacy of the resection, medical therapy should be reinstituted and consideration given to reoperation in cases of further unremitting hypoglycaemia. Reoperation consists of near total (95%) pancreatectomy with preservation of the distal bile duct and duodenum. Permanent exocrine or endocrine insufficiency is unusual in infants less than 3 months of age. This relates to the considerable regenerative capacity of the infantile pancreas.

Medical treatment

Antisecretory therapy with diazoxide is indicated for persistent hypoglycaemia in the preoperative phase and when operation is unsuccessful or contraindicated because of the poor condition of the patient. Diazoxide is a non-diuretic benzothiadiazine which inhibits the release of secretory granules from normal islet -cells and from insulinoma cells. Dosage is individualized based on effectiveness. Because of side effects such as oedema, bone marrow depression, hyperuricaemia, cardiomyopathy and hirsutism in females, patients on diazoxide require close medical supervision. Long-acting analogues of somatostatin are used in the treatment of hyperinsulinism in inoperable patients with insulinoma. Somatostatin both inhibits secretion of peptide by the hyperfunctioning islet cells or tumour and reduces target organ receptivity. In insulinoma patients, two-thirds obtain good symptomatic relief despite much lower rates of control of insulin levels. Few or no antitumour effects have been demonstrated with the use of somatostatin in malignant insulinoma. Streptozotocin, an antibiotic which selectively destroys pancreatic islet cells by inhibiting DNA synthesis, is the chemotherapeutic agent of choice for metastatic insulinoma. Objective tumour regression occurs in about 60% of patients and survival is doubled in those who respond to the drug. Streptozotocin is highly nephrotoxic and hepatotoxic and is thus not used as routine adjunctive therapy. Combinations of somatostatin, streptozotocin and diazoxide are often useful in treating functioning malignant insulinoma.

Gastrinoma (Zollinger–Ellison syndrome)

In 1955, Zollinger and Ellison described two patients, each having a syndrome consisting of fulminant intractable peptic ulcer disease, massive gastric acid hypersecretion, and a non-β-islet cell tumour of the pancreas. Although the same clinical triad had been reported previously, Zollinger and Ellison postulated that the gastric acid excess was caused by a humoral factor released from the tumour. While their original supposition had been that glucagon was the responsible factor, the peptide hormone gastrin was subsequently extracted from such tumours which were found to be of the non-β, non-α-cell type. A radioimmunoassay was developed for gastrin and the hormone was found to be markedly elevated in the plasma of patients with Zollinger–Ellison syndrome.

Clinical features and diagnosis of gastrinoma

The incidence of Zollinger–Ellison syndrome by best estimates is approximately one in 100 000, although the exact incidence is impossible to determine since no large population has been screened for the disease. The disease is more common in men than women with the male-to-female ratio being 3:2. The Zollinger–Ellison syndrome has been reported in patients ranging in age from 7 to 90 years, but the majority of patients have been diagnosed between the third and fifth decades. Only approximately one in 750 patients with the peptic ulcer disease will have gastrinoma as the aetiology.

About one-quarter of Zollinger–Ellison syndrome patients have their gastrinoma as part of the MEN-1 syndrome. MEN-1 is inherited as an autosomal dominant syndrome and the lesions most commonly associated with gastrinoma are parathyroid hyperplasia and pituitary prolactinoma. Gastrinomas in MEN-1 patients are less likely to be malignant but are almost always multifocal. This is in contrast to patients with sporadic gastrinoma in whom the disease is more often malignant but somewhat less frequently multifocal in origin. Overall, the gastrinoma is malignant in about one-half of patients and arises in the pancreas in about 75%. Even when benign, gastrinomas are more often multiple than solitary. The most common extrapancreatic primary tumour site is the duodenum. Tumours in this location are solitary in about one-half of cases. Much less commonly, primary gastrinomas are found in the omenta, lymph nodes, liver and gastric antrum. Malignant gastrinomas metastasize to regional lymph nodes and liver.

Peptic ulcer disease is present in over 90% of gastrinoma patients. Almost all patients with ulcers have typical dyspeptic pain which is more severe and less responsive to medical treatment than in routine peptic ulcer disease. Coexisting diarrhoea is a significant complaint in about one-third of gastrinoma patients. About 5–7% of patients have diarrhoea as their sole presenting complaint. Large volumes of watery stools may result in dehydration, potassium loss, weakness and wasting. The diarrhoea is of the secretory variety and frequently accompanied by steatorrhoea. A multifactorial aetiology has been elucidated but the basic underlying abnormality is acid hypersecretion. With the accompanying rapid gastric emptying, the large acid load in the duodenum and upper jejunum lowers the pH to cause inactivation of pancreatic lipase and other enzymes. This, in addition to the mucosal injury imparted by the large acid load, leads to malabsorption and steatorrhoea. There is also increased intestinal motility and inhibition of salt and water absorption from the jejunum due to the hypergastrinaemia. When severe, the mucosal injury of the distal duodenum and proximal jejunum manifests as frank peptic ulceration at these atypical sites.

The majority of patients with Zollinger–Ellison syndrome are diagnosed only after several years of symptoms, although increasing awareness of the disease is lowering the time between symptom onset and diagnosis. In the past, the majority of patients were diagnosed only after one or more failed operations for presumed routine peptic ulcer disease. Currently, many patients are being diagnosed prior to being subjected to ill-fated standard ulcer operations. All of the complications of peptic ulcer disease are encountered in Zollinger–Ellison syndrome patients and acute haemorrhage and perforation are each noted in approximately 20%. Vomiting and other symptoms of gastric outlet obstruction are distinctly less common as the fulminant nature of the ulcer diathesis more often precipitates acute complications. Wilfred Sircus of Edinburgh referred to patients with Zollinger–Ellison syndrome as 'recurrent ulcerators, persistent perforators, and bleeders unto death.' Severe, refractory reflux oesophagitis has been an underappreciated manifestation of the disease.

Patients with gastrinoma most often have no abnormal physical finding. However, signs of weight loss, epigastric tenderness and intestinal hypermotility are relatively common. Intra-abdominal tumour masses are rarely palpable but hepatic enlargement secondary to massive metastatic deposits is occasionally seen at initial presentation.

The diagnosis of Zollinger–Ellison syndrome should be considered in any patient having:

- severe peptic ulcer disease refractory to histamine H_2-receptor antagonists
- multiple peptic ulcers or ulcers in unusual locations such as the distal duodenum or jejunum
- peptic ulcer disease associated with diarrhoea
- recurrent peptic ulcer disease following an acid-reducing operation
- peptic ulcer disease in association with a strong family history of ulcer disease of MEN-1 syndrome
- peptic ulcer disease without prior diagnosis of MEN-1 syndrome but in association with any other component of MEN-1 syndrome (e.g. hypercalcaemia).

In addition, findings of large gastric mucosal folds and diffuse inflammation or frank ulceration distal to the duodenal bulb on endoscopic or radiological examination of the upper gastrointestinal tract are suggestive of the Zollinger–Ellison syndrome. In the presence of peptic ulceration and/or secretory diarrhoea, radioimmunoassay of the fasting plasma gastrin level remains the key to diagnosis of Zollinger–Ellison syndrome. A basal gastrin level greater than 100 pg/mL strongly supports the diagnosis of gastrinoma. The majority of patients have fasting levels greater than 200 pg/mL and not infrequently 1000 pg/mL or greater. It must be remembered that hypergastrinaemia can occur in association with gastric hypochlorhydria or achlorhydria from a variety of conditions not associated with gastrinoma. Patients with pernicious anaemia, chronic atrophic gastritis, gastric cancer, prior vagotomy or histamine H_2-receptor antagonist or omeprazole therapy may manifest hypergastrinaemia as a physiological response to an elevated antral pH. Thus, it is important to measure basal acid output in all patients suspected to have gastrinoma based on clinical presentation and an elevated plasma gastrin level.

The principal circulating form of gastrin in patients with gastrinoma is G-34 or 'big gastrin', a situation analogous to insulinomas and other peptide-producing endocrine tumours where elevated levels of precursor forms of the respective hormones are often found. The measured circulating gastrin level does not reflect the degree of gastric acid stimulation by the tumour, nor is there good correlation between gastrin level and tumour mass. Plasma gastrin levels normally rise following a meal and thus measurements must be made in the fasting state. Gastric outlet obstruction secondary to ordinary duodenal ulcer disease, antral G-cell hyperfunction or hyperplasia, and retained gastric antrum after Billroth II gastrectomy are other conditions associated with peptic ulcer in which elevated basal plasma gastrin levels may be found (Box 27.4).

In order to differentiate these entities from gastrinoma and also to establish the diagnosis of gastrinoma in ulcer patients with borderline elevated basal gastrin levels, a number of provocative tests have been devised. The best of these is the secretin stimulation test. Following intravenous injection of secretin (2 U/kg), the plasma gastrin level rises within 5–10 minutes to a level 200 pg/mL greater than the basal level in patients with gastrinoma, but not in those with other conditions. The calcium stimulation test has also been used to differentiate gastrinoma from ordinary peptic ulcer disease. In this test calcium is infused at 5 mg/kg/h for 3 hours and a positive test requires that the stimulated gastrin increases by 100% over basal level. Because of untoward side effects of hypercalcaemia, long duration of the test and slightly lower accuracy, the calcium infusion test has been almost entirely supplanted by the secretin injection test. The meal provocation test may be used to differentiate gastrinoma from antral G-cell hyperfunction. In this test, a standard meal is ingested by the patient and causes a marked rise in plasma gastrin levels in those with G-cell hyperfunction but no rise or only a minimal one in gastrinoma patients.

BOX 27.4 Differential diagnosis of hypergastrinaemia

With acid hypersecretion

- Zollinger–Ellison syndrome
- Retained gastric antrum after Billroth II gastrectomy
- Antral G-cell hyperplasia
- Gastric outlet obstruction

With acid hyposecretion

- Pernicious anaemia
- Atrophic gastritis
- Gastric cancer

In order to secure the diagnosis of gastrinoma in patients demonstrated to have hypergastrinaemia, gastric acid secretory testing is necessary. A basal level output greater than 15 mmol/h strongly supports the diagnosis, as does a value greater than 5 mmol/h in the patient with previous acid-reducing gastric surgery for peptic ulcer disease. A ratio of basal acid output to maximal acid output following stimulation with pentagastrin, histamine or betazole of greater than 0.6 has also been used as a discriminatory criterion for gastrinoma. However, this ratio is no more sensitive or specific than is the basal acid output alone. Upper gastrointestinal endoscopy and a standard barium upper gastrointestinal radiological series should be performed in all patients thought to harbour a gastrinoma. In addition to the mucosal abnormalities often found with these studies, on rare occasions a duodenal or antral polypoid lesion has proved to be a gastrinoma on biopsy.

All patients diagnosed as having Zollinger–Ellison syndrome should be further investigated for the presence of MEN-1 syndrome. In addition to the plasma gastrin determinations, several serum calcium and phosphate measurements and a plasma prolactin level constitute the absolute minimal work-up for the most commonly associated endocrine lesions. A family history of refractory ulcer disease, hyperparathyroidism or other endocrine lesions warrants endocrinological screening of the immediate family as well as the patient. The diagnostic approach to the patient with suspected gastrinoma is summarized in Figure 27.27.

Tumour localization techniques

Preoperative techniques to localize gastrinomas are not particularly successful. Since gastrinomas may be small and deeply embedded in the pancreas, abdominal ultrasonography, CT and MRI have not been very sensitive. Recent information, however, suggests that 30–50% of gastrinomas can be identified with multidetector helical CT scanners and EUS. Nonetheless tumours smaller than 7 mm are not usually visualized. Since most gastrinomas are hypovascular, visceral angiography has been much less useful in localizing gastrinomas than insulinomas.

Both EUS and octreoscan have been useful in detection of gastrinomas and other neuroendocrine tumours. The combination of both increases the sensitivity. The sensitivity of EUS is endoscopist dependent but reported detection rates range from 70% to 94%, significantly higher than CT or MRI scanning. Octrescan has its limitations; a high density of somatostatin sstr2 receptors is a necessity. Other tumours or tissues may create a false-positive result. Active infection, inflammation or recent abdominal surgery limits the utility of octrescan. However, these diagnostic tests, if available, can be invaluable preoperatively.

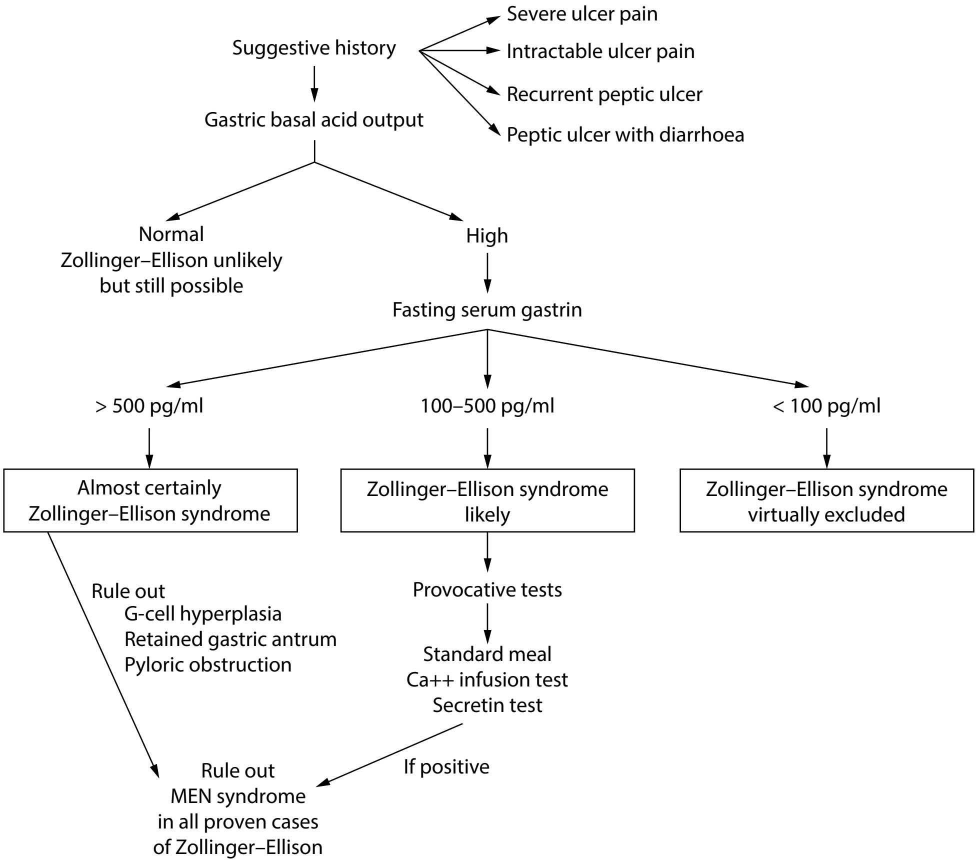

Figure 27.27 An approach to the investigation of patients with suspected Zollinger–Ellison syndrome.

The best results on the preoperative localization of gastrinomas (pancreatic and duodenal) reported in recent years have been with EUS. In one series of 22 patients with Zollinger–Ellison syndrome who underwent exploratory laparotomy after preoperative attempts at localization of the gastrinoma(s) by CT, upper gastrointestinal endoscopy and EUS, the last was by far the most effective. In this study, surgical exploration included intraoperative ultrasonography and duodenal transillumination. The sensitivity of EUS was 50% for duodenal wall tumours, 75% for pancreatic tumours and 62.5% for metastatic lymph nodes. The combination of conventional endoscopy and EUS provided correct preoperative diagnosis in 60% of the patients. This and other reports indicate that EUS should be considered as the first choice of imaging for preoperative detection of gastrinomas.

Percutaneous transhepatic selective sampling of the portal venous system for gastrin levels has been touted to be of value in gastrinoma patients. In theory, the technique is intended to localize the source or sources of hypergastrinaemia and, when combined with hepatic venous gastrin level sampling, predict the location of tumours and the presence or absence of hepatic metastases. Since up to 85% of gastrinomas have been found to reside within the anatomic gastrinoma triangle containing the duodenal C-loop, the head of the pancreas and their associated regional lymph nodes, transhepatic portal venous sampling can only be expected to locate tumours within the triangle but not to localize them more precisely. Therefore, the test is of limited practical utility for gastrinoma.

In general, presently available preoperative tests do not appear capable of localizing the tumour any more reliably than careful intraoperative exploration by the experienced surgeon. Intraoperative contact ultrasonography and transillumination through a flexible endoscope (for duodenal tumours) are valuable in the localization of small tumours. Together with intraoperative contact ultrasound scanning, this should be a routine part of the exploration and may obviate the need for duodenotomy in some cases.

Surgical treatment

In view of their rarity, gastrinomas should be treated in specialized tertiary referral centres. Their management depends on whether they are associated with MEN-1, some of which are treated medically, or are sporadic gastrinomas (not associated with MEN-1) which should always be considered for surgery. In the latter instance, a thorough preoperative assessment of the location and extent of disease is essential (Figure 27.28).

With the advent of effective acid suppression especially by proton pump inhibitors, the role of surgery in the management of patients with Zollinger–Ellison syndrome has changed from surgical treatment of the severe ulcer diathesis resulting from persistent inappropriate acid hypersecretion to improvement of long-term survival by addressing the predominantly malignant nature of primary gastrinomas (90%) despite their slow growth. Total gastrectomy is seldom performed except in exceptional circumstances: patients unable to attend

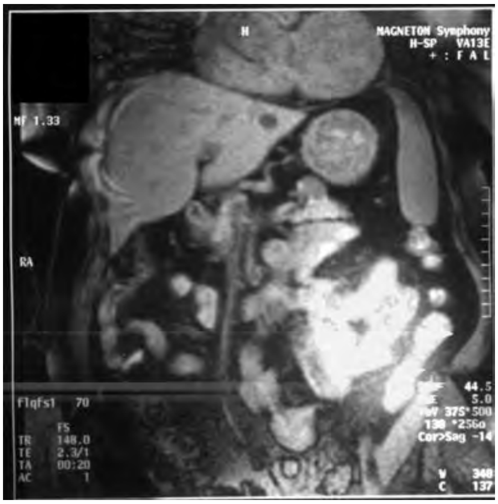

Figure 27.28 Preoperative MRI showing a large pancreatic (2.0 cm) gastrinoma with solitary deposit in the liver. The patient remained free of disease and without need of acid suppression therapy after pancreaticoduodenectomy and hepatic segmental resection.

routine medical follow-up or those with proven failed medical acid suppression or non-compliance with oral medication.

In patients with Zollinger–Ellison syndrome and MEN-1 with hypercalcaemia due to hyperparathyroidism, parathyroidectomy is indicated before any other surgical procedure is contemplated. Parathyroidectomy reduces the serum gastric level in these patients and improves efficacy of medical acid suppression therapy. Surgical resection of gastrinoma is indicated in all patients with sporadic Zollinger–Ellison syndrome who are fit for surgery. Indeed there is some evidence that surgical resection may alter the natural history of the disease since only a small percentage of patients with resected lesions develop liver metastases during follow-up, as distinct to those treated medically. Acid suppression with proton pump inhibitor therapy is established before surgery. At laparotomy a thorough exploration of the pancreas and duodenum (complete Kocherization) is done together with contact ultrasonography and duodenal transillumination via intraoperative upper gastrointestinal endoscopy in the search for the gastrinoma(s). Most surgeons would also perform a duodenotomy if a pancreatic lesion is not found. The search should also extend to examination of regional lymph nodes and metastasis in the liver. Gastrinoma in the pancreatic head is treated by enucleation when possible but a pancreaticoduodenectomy is indicated if the lesion is large or when encucleation would compromise the integrity of the main duct of Wirsung. Hepatic deposits should be excised by appropriate anatomic resection (usually segmentectomy) at the time of resection of the gastrinoma. The long-term outcome of Zollinger–Ellison syndrome patients following curative surgical treatment (Ro) for sporadic gastrinoma (pancreatic or duodenal) is good with 34% being free of disease at 10 years and an overall 10 year survival greater than 80%. A persistently normal postoperative fasting serum gastrin significantly predicts cure. The most important predictor of disease-free survival is histological lymph node status. Reoperation is indicated in patients with sporadic Zollinger–Ellison syndrome who develop persistent or recurrent disease. The site of recurrent disease has to be identified at reoperation (pancreatic, duodenal, metastatic nodal disease of liver deposits) and the disease resected or debulked whenever possible.

The role of surgical treatment in patients with Zollinger–Ellison syndrome associated with MEN-1 is less standardized. Cure is unlikely in these patients because of the high incidence of multiple tumours (80%) and metastatic deposits in lymph nodes at the time of diagnosis of Zollinger–Ellison syndrome. Thus relapse after surgery occurs in the vast majority of patients within 3–5 years. Nonetheless, the prognosis is still good in these patients with or without surgical treatment. The current recommendation is to operate on patients with MEN-1 and Zollinger–Ellison syndrome with large tumour (2.5 or more) as these patients are likely to have metastatic disease.

In view of the above, there is consensus on the following management for newly diagnosed gastrinoma patients.

Patients with preoperatively documented liver metastases and/or MEN-1 syndrome are treated medically in the first instance, especially patients with multiple liver deposits or patients with MEN-1 who have multiple primary tumours. Total gastrectomy is performed if these patients fail medical therapy. During this operation confirmation of the multifocal nature of the disease is obtained by biopsies of suspected tumours.

Young to middle-aged patients without known liver metastases are subjected to the tumour localization and offered elective laparotomy with the primary intent of complete radical excision including regional lymph nodes. This exploration requires full mobilization of the pancreas and the duodenum. All identified lymph nodes and palpable masses within and around the pancreas are removed and submitted for frozen section histology. Blind distal pancreatectomy is not advocated as most tumours occur in and around the head of the pancreas.

Patients responding poorly to antisecretory drugs, or who are non-compliant, and at exploration no tumour is found or multifocal disease is present are treated by elective total gastrectomy which should carry a low mortality (under 5%).

Medical treatment

Since the majority of gastrinomas are malignant, surgical therapy directed at the primary and metastatic disease is indicated in patients with sporadic Zollinger–Ellison syndrome, even if acid suppression is effective.

Currently proton pump inhibitors (omeprazole, lanzoprazole, etc.) have largely replaced H_2-antagonists (cimetidine, ranitidine, famotidine) in acid suppression therapy for the Zollinger–Ellison syndrome. These patients require higher doses (two to four times) that of patients with peptic ulcer disease or gastro-oesophageal reflux. The dose has to be established for the individual patient and not infrequently (25% of patients) increase in dose is necessary over time. Medical acid suppression alone is used more often in patients with Zollinger–Ellison syndrome associated with MEN-1 syndrome with multiple tumours and poor general health.

Treatment of hepatic metastases

Hepatic metastatic disease is usually managed with surgical resection, but other modalities have been used, e.g. hepatic regional arterial infusion and radiofrequency ablation. Liver transplantation may be considered in patients with extensive liver disease but without evidence of extrahepatic deposits in view of the slow growth of these tumours. Somatostatin receptor-directed therapies such as octreotide and radiolabelled octreotide have been used but the reported results are variable.

Systemic chemotherapy is usually with cisplatin and Adriamycin or streptozotocin and 5FU as the last resort in patients with inoperable disease but the results are poor.

VIPoma (Werner–Morrison syndrome; WDHA syndrome; pancreatic cholera)

The syndrome of watery diarrhoea, hypokalaemia and achlorhydria (WDHA) in association with an islet cell tumour of the pancreas was initially described by Werner and Morrison in 1958. A number of hormones have been identified in these tumours (including secretin, glucagon, gastric inhibitory polypeptide, PP and gastrin). However, VIP has been convincingly shown to be the causative agent in the majority of cases. There are occasional patients, however, who have the identical clinical syndrome but with normal plasma VIP levels. In these cases, prostaglandin E is the most likely aetiological candidate. Because this condition resembles cholera, it is also known as pancreatic cholera. A small percentage of patients also have hypercalcaemia, hyperglycaemia, hypochlorhydria and flushing. The condition may be associated with MEN-1. VIP stimulates pancreatic, intestinal and gallbladder water and electrolyte secretions as well as pancreatic enzyme secretion and colonic potassium secretion. VIP inhibits absorption of water and electrolytes (sodium, chloride, bicarbonate and potassium) in the small intestine and colon and also inhibits acid and pepsin secretion in the stomach.

These tumours are usually intrapancreatic, although ectopic primary sites (liver and jejunum) can occur in about 10% of patients. In children, the VIPoma syndrome may be caused by a ganglioneuroma or ganglioneuroblastoma. The diarrhoea in patients afflicted with WDHA is secretory in nature, profuse and causes severe dehydration and loss of potassium. Acidosis almost invariably attends the hypokalaemia and patients suffer from lethargy and weakness as a result of the dehydration and electrolyte abnormalities.

Pathology

VIPomas are composed of sheets of small round cells with uniform nuclei and cytoplasm and rare mitotic figures. They contain electron-dense granules which are due to various tumour products: amines, neuron-specific enolase, synaptophysins, α- and β-subunits of human chorionic gonadotrophin, and chromogranins A, B and C. These tumours frequently are multihormonal, i.e. containing more than one hormone. Unlike insulinomas, VIPomas are generally large in size (>3.0 cm) at the time of clinical presentation, with 50% being malignant though slow growing. The primary tumour is located in the body and tail of the pancreas in approximately 75% of cases and is almost always solitary. The extrapancreatic VIPomas include ganglioneuromas and neuroblastomas and are capable of causing the identical clinical syndrome. Unlike pancreatic tumours which also secrete PP, the extrapancreatic tumours do not.

The pathology of WDHA syndrome is related to the actions of VIP which is normally secreted from non-β-islet pancreatic cells in response to food containing fat, proteins and alcohol. VIP relaxes smooth muscles of the gastrointestinal tract (decrease in lower oesophageal sphincter pressure, relaxation of the gastric antrum and body, inhibition of gallbladder and intestinal circular muscle contraction). VIP has many pharmacological actions: positive inotropic action on the heart; vasodilatation; increase in intestinal water and electrolyte secretion; inhibition of gastrin and gastric acid secretion; and stimulation of pancreatic secretion, lipolysis and glycolysis. Studies have implicated several genes, including the *MEN1* gene, *p16/MTS1* tumour suppressor gene, *DPC4/Smad 4* gene; amplification of the *HER2/neu* proto-oncogene and a possible tumour suppressor gene on chromosome arm 3p. Alterations in the *MEN1* gene and the *p16/MTS1* tumour suppressor gene seem to be particularly involved in the pathogenesis of VIPoma. There is evidence that *p16/MTS1* tumour suppressor gene alterations located on chromosome arm 9p21 occur in a significant percentage of pancreatic endocrine tumours including VIPomas. These mutations result in loss of cell cycle inhibition.

Clinical features

VIPomas are rare pancreatic islet cell tumours, with an estimated incidence of 0.05–0.2 per million population. Their incidence is one-eighth that of insulinomas. The age at diagnosis has a bimodal distribution: children (from 10 months to 9 years) and adults (32–81 years). Diarrhoea is the most common symptom and occurs in at least 90% of patients. The diarrhoea can be associated with abdominal cramps and is voluminous with stool output >3 L/day. It is secretory in nature and persists during fasting. Weight loss occurs in the majority of patients. Abdominal pain is present in 50% and flushing is observed in 20% of patients. Apart from signs of chronic ill health and volume depletion, there are usually no physical findings except for flushing episodes. The definitive diagnosis of WDHA syndrome requires:

- the presence of secretory diarrhoea
- stool volume greater than 700 mL per day
- identification of a pancreatic endocrine tumour
- fasting VIP levels above 190 pg/mL.

Hypokalaemia is present in 90–100% of patients and is secondary to the heavy faecal losses of potassium. Patients often have coexisting hypomagnesaemia and non-anion gap metabolic acidosis, reflecting the severity of the diarrhoea. Hyperglycaemia occurs in 25–50% and is secondary to the glycogenolytic effect of VIP on the liver. Hypercalcaemia occurs in 25–76%. About 6% of these patients have associated MEN-1 syndrome with resultant hypercalcaemia secondary to hyperparathyroidism. Tumours causing hypercalcaemia are almost always malignant. All patients have stool volumes greater than 700 mL/day, and often much higher. The diagnosis of WDHA is suspect if the stool volume is less than 700 mL/day. The diarrhoea in WDHA syndrome is secretory with a stool osmotic gap of less than 50 mEq/L.

Tumour localization

Conventional imaging studies detect fewer than 60% of primary tumours. SRS using indium-diethylene triamine pentacetic acid-phenylalanine (In-DTPA-DPhe) octreotide is the most sensitive modality for identifying the primary tumours and metastatic disease. However, some 12% of positive SRS scans are falsely positive due to the presence of somatostatin receptors in normal tissues. Additional imaging with MRI and selective angiography is however helpful in defining the location of liver metastases. PET is useful for tumour localization, and, when used with ^{18}F-fludeoxyglucose, it may predict malignancy in poorly differentiated tumours. EUS is extremely useful and is considered complementary to SRS scanning in the investigation of patients. If the SRS scan is negative, EUS is performed as it can detect intrapancreatic tumours greater than 0.5 cm. Selective angiography with hepatic venous sampling is indicated when both SRS and EUS are negative. Intraoperative contact ultrasound scanning is recommended during surgical exploration because it may help identify additional tumours that were not detected preoperatively.

Medical treatment

In the first instance, medical treatment is directed at treating symptoms caused by the persistent hypersecretion of VIP with vigorous rehydration and correction of electrolyte and acid–base abnormalities. This can be life saving, since the most common cause of death in VIPoma patients is acute renal failure associated with hypokalaemia. Somatostatin is used to control diarrhoea and may reduce the tumour size in a minority of patients. Somatostatin offers rapid symptomatic control in 90% of patients with marked amelioration of the diarrhoea, dehydration and their attendant metabolic sequelae. Typically, VIP levels decrease but do not fall to within the normal range, suggesting that the attenuation of symptoms is due in considerable degree to reduced target receptivity to the hormone. Slow-release preparations, e.g. lanreotide and sandostatin LAR; are used in preference to octreotide nowadays. Antidiarrhoeal medication such as loperamide may be used in addition to somatostatin in patients with breakthrough diarrhoea. Once the situation of the patient is stabilized, investigation to identify and locate the tumour is carried out if the serum VIP level is elevated.

Surgical treatment

Surgical resection offers the only chance for cure, but the tumour has often spread to regional lymph nodes and/or to the liver by the time of diagnosis. Even so palliative resection of the primary tumour with removal of regional lymph nodes and resection of hepatic metastases can provide substantial palliation. Surgical resection is the only potential cure as 50–60% of VIPomas are malignant. Thus all fit patients should be considered for exploratory laparotomy. The operation starts as an exploration during which the liver is examined for metastatic disease. Next a careful examination of the entire pancreas is carried out with complete Kockerization of the duodenum and incision of the retroperitoneum along the superior and inferior aspects of the pancreas. Mobilization of the spleen may be required in order to examine the pancreatic tail. Additionally, the small bowel should be explored for extrapancreatic tumours. Although VIPomas are usually intrapancreatic, 10% of tumours are ectopic along the ganglia of the autonomic nervous system.

Intraoperative contact ultrasound is extremely useful and may identify lesions not detected preoperatively. Isolated tumours in the pancreatic body or tail are removed by distal pancreatectomy, with or without splenectomy. More proximal tumours in the pancreatic head or body may be treated by enucleation. However, the most common operation performed for proximal tumours is pancreaticoduodenectomy.

Patients with resectable disease have a 5 year survival rate as high as 80%, as distinct from patients with incompletely resected/ or unresectable disease in whom the 5 year survival drops to 25%. However, cytoreductive/debulking surgery may prolong life expectancy. Liver transplantation for metastatic liver disease is considered in patients who are fit and free of extrahepatic disease.

Palliative chemotherapy

Patients who are beyond treatment by surgical resection, or who recur with multiple metastatic deposits, may have symptomatic responses to long-acting somatostatin analogues. Streptozotocin is reasonably effective in palliation but, immediately following administration, diarrhoea and electrolyte losses may be exacerbated for several days, necessitating aggressive replacement. The prognosis is poor with advanced disease, and thromboembolic complications due to excessive dehydration add to the morbidity and mortality. The occasional patient with pancreatic cholera secondary to prostaglandin E2 hypersecretion may have dramatic relief with indometacin therapy.

Aside from streptozotocin, several chemotherapeutic agents have been used to treat patients with metastatic disease but streptozotocin and doxorubicin are the most effective. Other agents include 5FU and a combination of interferon-α and 5FU. Radiologically guided therapies include hepatic artery occlusion, with or without chemotherapy, chemoembolization with doxorubicin in iodized acid combined with gelatin or sponge particles.

Glucagonoma

Glucagonomas are tumours of the A-cell of the pancreatic islet and are responsible for a characteristic syndrome consisting of severe skin rash, weight loss, diabetes mellitus, deep venous thrombosis, anaemia and hypoaminoacidaemia. The tumour is very rare and because its most salient feature, the skin rash, is frequently misdiagnosed, its true significance and the correct diagnosis are often made very late in the course. As expected, the disease is virtually always first seen in the dermatology clinic. Glucagonoma is considerably more common in females and is a disease of middle age. At the time of diagnosis approximately 60–70% of cases have already metastasized. The most common site of metastasis is the liver (50%). The typical clinical features of the glucagonoma syndrome are shown in Table 27.7.

Table 27.7 Clinical features of glucagonoma syndrome

Sex	Female/male >1
Age range (mean)	20–71 (57)
Malignancy	70–80%
Clinical diabetes (abnormal glucose tolerance test)	70% (95%)
Skin lesions	80%
Glossitis/cheilitis	90–100%
Weight loss	90–100%
Diarrhoea	50–60%
Coarse intestinal mucosal folds	50–60%
Anaemia, normocytic, normochromic	70–80%
Hypoaminoacidaemia	80%
Neurological deficit	Unusual (incidence uncertain)
Marked hyperglucagonaemia	100%
Survival	80% more than 2 years
	23% more than 5½ years

The typical skin rash is termed necrolytic migratory erythema. The lesions are characteristically symmetrical and erythematous with crusted erosions involving the perineum, groins, thighs, buttocks and distal extremities. The systemic manifestations of weight loss, weakness and lethargy are due to a combination of the catabolic effects of high plasma glucagon levels and the extensive malignant disease which is often present. Hyperglycaemia results from increased hepatic glycogenosis and gluconeogenesis. Most patients are frankly diabetic but ketonaemia rarely develops because circulating insulin levels are increased. Panhypoaminoacidaemia is a uniform finding and may be responsible for the skin rash as well as the neurological deficits that are occasionally seen. The anaemia is characteristically normocytic and normochromic and, although serum iron levels may be low, the anaemia does not respond to iron and vitamin replacement.

The diagnosis is usually made upon recognition of the typical cutaneous manifestations in combination with diabetes mellitus in the setting of a chronic wasting disorder. The diagnosis is confirmed by finding an elevated plasma glucagon level. Normal values range between 50 and 150 pg/mL. Values of glucagon greater than 1000 pg/mL are often seen with glucagonoma but interpretation should be cautious in the absence of the typical skin rash or other suggestive signs. The numerous other conditions associated with hyperglucagonaemia include:

- diabetes, ketoacidosis, hyperosmolar syndrome
- chronic renal failure
- shock states:
  - myocardial infarction
  - septicaemia
  - burns
  - hypovolaemia/haemorrhage
- acute pancreatitis
- cirrhosis
  - portosystemic shunting (natural, surgical)
- glucagonoma
- familial hyperglucagonaemia (asymptomatic)
- exercise
- antiglucagon antibodies in diabetics treated with insulin.*

In most glucagonoma patients glucagon release from the tumour can be induced by the administration of arginine or tolbutamide. PP levels are elevated in one-half of patients. Since many cases are diagnosed in an advanced metastatic stage, tumour localization is not normally difficult. CT, angiography, EUS, MRI and octreotide scintigraphy have all been used successfully in localizing tumours. While topical steroids and intravenous amino acid administration have been effective in ameliorating the skin eruption in some patients, definitive treatment is surgical. Operative exploration is indicated even for advanced metastatic disease as debulking procedures may significantly alleviate the debilitating catabolic effects of the excess glucagon. When surgical resection is not an option, selective arterial embolization and chemotherapy are indicated. Streptozotocin combined with 5FU can produce a reduction in both tumour size and glucagon levels. Dimethyltrizenoimidazole carboxamide has been effective in providing symptomatic relief and alleviation of skin rash. Somatostatin has proved highly efficacious both in the preoperative management and as palliative therapy in glucagonoma. Octreotide or, more usually, its long-acting analogues reduce circulating glucagon levels, dramatically improve the skin rash, attenuate the systemic symptoms and augment the anabolic effects of intravenous hyperalimentation. Use of the somatostatin analogues is indicated in all cases regardless of the stage of disease or surgical plan. Unfortunately, no effects on tumour size or growth have been demonstrated. Similarly, interferon-α has been used with some success. This induces an autoimmunity against the tumour. This treatment is not curative, but it can prolong survival and control the symptoms of the disease. Combination treatment with interferon-α and somatostatin or chemotherapy has shown synergistic or additive beneficial effects in some patients with glucagonoma and other neuroendocrine malignancies.

Somatostatinoma

Somatostatinoma is a very rare tumour with less than 90 cases reported to date. The patients have been mostly middle-aged. The patients with pancreatic somatostatinoma are predominantly female. Over 80% of the tumours have been associated with liver metastases at the time of diagnosis. Along with somatostatin production most tumours elaborate other hormones in addition, such as VIP, PP, gastrin, calcitonin or cortisol.

Despite the potent inhibitory nature of somatostatin, the usual clinical syndrome is non-specific. Abdominal pain is the most common presenting symptom and this may relate to the high prevalence of cholelithiasis in these patients. Gallbladder stasis is thought to be of aetiological importance. Other symptoms and signs commonly associated with somatostatinoma are diarrhoea, diabetes mellitus (25%), weight loss, anorexia, hypochlorhydria, steatorrhoea and anaemia. Symptoms not related to excessive somatostatin levels such as tachycardia, flushing, hypertension,

---

* These may be induced by slight glucagon impurities in commercially available insulins and manifest as hyperglucagonaemia when glucagon is measured by a double antibody immunoassay method.

hypokalaemia and hypoglycaemia are also present in some patients. The diagnosis is made by chance in most cases although a radioimmunoassay for plasma somatostatin is available. Somatostatin released by the tumour may be stimulated by tolbutamide; however, the utility of this provocative test is unknown at present.

Ideally, treatment is by surgical excision of the pancreatic or duodenal lesion. Debulking of advanced tumours may be efficacious and some patients have benefited from adjunctive therapy with streptozotocin and 5FU. The 5 year survival rate after diagnosis of somatostatinoma is only about 15%.

Pancreatic polypeptide tumour (PPoma)

PP was discovered in 1972 as a single major protein from a crude insulin preparation. In mammals, 93% of the cells producing PP are located in the pancreas and are known as F or D2 cells. There is an association between increased PP levels and increased intra-abdominal but not subcutaneous fat, as measured by CT scan. A clear-cut biological role for PP has not been established. The only physiological effects recognized in humans are the inhibition of gallbladder contraction and pancreatic enzyme secretion. Thus, a tumour originating from PP cells is likely to be clinically silent. High levels of PP reduce both appetite and food intake in normal healthy volunteers indicating that PP may be a satiety hormone. PP is also secreted by other islet cell tumours in addition to their specific hormones, especially after stimulation by a meal. PP is thus now considered as a useful adjunct marker in the detection of islet cell tumours. PP-producing tumours are mostly located in the pancreas and may present as three pathological lesions: (1) pure PPomas, (2) mixed tumours with minor PP cell population and (3) PP-cell hyperplasia. These tumours are among the most common multiple adenomas found in patients with multiple endocrine neoplasia type 1. Numerous types of extrapancreatic endocrine tumours are able to synthesize and secrete PP. They occur mostly but not exclusively in the gastrointestinal tract, particularly in the rectum. The inactivation of the *MEN1* gene at 11q13 appears to be involved in the development of pancreatic but not of rectal PP-producing tumours.

Basal concentrations of PP in plasma may be raised above 1000 pg/mL in 22–77% by all endocrine-secreting tumours but are invariably normal in patients with ductal adenocarcinomas of the pancreas. The accuracy of raised basal PP concentration as a marker for endocrine-secreting tumours can be increased by determining the response of PP to secretin administration: a response of greater than 5000 pg/min/mL is considered abnormal (greater than two standard deviations observed in healthy subjects). Many cases of so-called non-functional endocrine tumours are now thought to be PPomas, because 50–75% of them have raised basal PP levels and an exaggerated response to secretin. Thus, in the absence of chronic renal failure which causes marked elevation of PP, markedly raised PP levels in otherwise healthy patients may indicate a non-functioning pancreatic endocrine tumour. Atropine suppression of PP has been suggested as a method of determining whether the elevated hormone is the result of tumour secretion.

PPomas are rare and are not associated with a clinical syndrome, despite the fact that they are functional and secrete high levels of PP. The tumours are usually single and benign, although a few have metastasized to the liver. There are now at least 25 patients in the literature with PPomas with an age spanning 20–74 years (mean of 51 years) and with an equal sex incidence. Diarrhoea occurs in one-third of cases, whereas steatorrhoea is universal in patients in whom it is sought. Decreased acid secretion is rare but 60% of patients present with weight loss. Some patients exhibit a pruritic rash. Otherwise the PPoma syndrome is silent, and these tumours often discovered during investigation of patients with hepatomegaly (metastases), abdominal pain, obstructive jaundice and haematochezia. Upper gastrointestinal bleeding may occur due to invasion of the wall of the duodenum or thrombosis of the splenic or portal vein, with consequent development of varices. PPomas are recognized by arteriography as highly vascular tumours with or without metastases to the liver. Twenty-five per cent of PPomas are associated with MEN-1 syndrome. In general however PPomas have a relatively benign clinical course with a low recurrence rate following excision at 5 years. The frequency of malignancy of PPomas is not established.

It has been suggested that every patient with a markedly elevated level of PP should undergo exploratory laparotomy with careful inspection of the pancreas. If a tumour is identified it is excised and the resection and extent will depend on site and size of the lesion. This practice is disputed by others as, although rare, PPomas may occur in the chest and elsewhere outside the pancreas. With this treatment policy which appears more logical, somatostatin receptor scintigraphy and EUS should be performed preoperatively to locate the tumour in patients with elevated PP. The findings of these imaging tests then dictate whether a laparotomy or other exploration is necessary. Metastatic PPomas are best treated with streptozotocin plus doxorubicin.

Multiple endocrine neoplasia type 1 syndrome (MEN-1; MEA-1; Werner syndrome)

The MEN-1 syndrome is inherited as an autosomal dominant disorder but considerable phenotypic variability exists even within an individual family. However, the pancreas, parathyroid glands and pituitary are involved in all patients if examined pathologically. The pancreas is inevitably involved with diffuse islet cell disease consisting of micronodular and macronodular hyperplasia, and often multiple tumours secreting multiple peptide hormones.

The parathyroid glands are most frequently involved in MEN-1 syndrome with hyperparathyroidism being present in 85% of cases. In the vast majority of these all four glands are affected. This is in contrast with the very low incidence of parathyroid hyperplasia in isolated primary hyperparathyroidism. Pancreatic abnormalities occur in over 80% of MEN-1 patients, with non- -cell tumours being most common. The most common pancreatic tumour found in MEN-1 syndrome patients is gastrinoma, and in virtually all such patients multiple pancreatic tumours are found.

Of the pituitary lesions, chromophobe adenomas and particularly prolactinomas are the most frequent lesions encountered. When small, these tumours may be without symptoms but, in male patients, they are associated with manifestations of the antiandrogenic effect of prolactin. Tumours producing growth hormone and leading to acromegaly are the next most frequently encountered variety.

While the MEN-1 syndrome is classically associated with lesions of the parathyroid glands, pancreatic islets and pituitary gland, an increasing number of adrenocortical lesions have been recognized. Many of these lesions are non-functioning adenomas; however, glucocorticoid excess has been reported in some. Other occasional associations of MEN-1 include thyroid nodules, bronchial and intestinal carcinoids and lipomas.

All patients with endocrine pancreatic tumours should be carefully investigated for additional manifestation of MEN-1 syndrome. Thus, estimations of serum levels of calcium and phosphate as well as plasma assays for parathormone, insulin, gastrin, glucagon, somatostatin, PP, prolactin, growth hormone, ACTH and cortisol constitute a relatively complete though by no means exhaustive endocrine evaluation for the MEN-1 syndrome. Whenever a patient is diagnosed as having MEN-1 syndrome, screening of all available family members is indicated.

Multiple endocrine neoplasia type 2 syndrome (MEN-2; MEA 2; Sipple syndrome)

MEN-2 is another discrete endocrine syndrome which is inherited as an autosomal dominant syndrome with variable expressivity. It is not associated with pancreatic disease. It consists of hyperparathyroidism, medullary carcinoma of the thyroid gland and phaeochromocytoma. MEN-2b is a variant which is also inherited as an autosomal dominant syndrome but, unlike in MEN-2, the incidence of parathyroid disease is extremely low. The syndrome consists of multiple mucosal neuromas, intestinal ganglioneuromatosis leading to megacolon and constipation, a Marfanoid habitus and characteristic facies with thickened lips and alae nasi, along with medullary carcinoma of the thyroid and phaeochromocytoma.

CHAPTER 28

Bariatric surgery

AHMED R. AHMED AND CAREL L.G. ROUX

Obesity

The problem of obesity: obesity-related diseases, life expectancy and health costs

The World Health Organization (WHO) estimated that globally in 2011 approximately 2 billion adults were overweight and at least 500 million were obese. In almost all developed countries and in many developing ones, obesity rates have risen dramatically. According to the Information Centre for the NHS in 2011, 24% of adults (aged 16 years or older) in England were classified as obese. This has nearly doubled since 1993. Women are more likely to be morbidly obese (3% compared with 1% of men). The implications are that 21% of males and 23% of females are classed as being at very high risk of obesity-related health disease.

Obesity and being overweight can have a variety of adverse health consequences associated with a high rate of premature death, such as type 2 diabetes, dyslipidaemia, hypertension, obstructive sleep apnoea, certain types of cancer, steatohepatitis, gastro-oesophageal reflux, arthritis, polycystic ovary syndrome (pcoss) and infertility. The life expectancy of a severely obese person is reduced by an estimated 5–20 years. An estimated 2.6 million people die each year as a result of being overweight or obese and the consequences of excess weight will soon rival tobacco as the world's leading cause of preventable premature deaths.

The obesity pandemic also has significant economic consequences. The WHO estimates that, in many developed countries, obesity now accounts for 2–7% of all healthcare spending. Yet medical costs are only a small fraction of the pandemic's total costs. Among its other adverse economic effects are heightened absenteeism rates, reduced worker productivity, and increased food and clothing costs.

Pathophysiology of obesity

The laws of thermodynamics plainly state: energy will be stored if more energy is consumed than expended. The storage is usually in the form of adipose tissue and it has been calculated that the average man living in the USA increases his weight by more than 9.1 kg between the ages of 25 and 35. This dramatic weight accumulation is due to only a 0.3% imbalance between energy consumed and expended during this period. A suggestion that the obesity pandemic is due to a more sedentary lifestyle is based on the fact that several studies could not find a significant increase in the amount of calories consumed over the last few decades. The suggestion that the current situation can be remedied by increasing exercise levels seems to be prone to failure for several reasons. First, the human body is extremely efficient when it comes to energy expenditure. The average man who finishes a marathon in 4.5 hours will burn only 2072 kcal, approximately the same amount of energy he would normally be expected to consume during a day. Even allowing for the increased energy expenditure that follows exercise, he would have to run a marathon every 10 days while not increasing his energy intake if he hoped to lose 1 kg a month. Second, our daily surroundings have been optimized to allow us to spend the minimum amount of energy. This includes a reduced energy expenditure required, for example using the motor car instead of public transport, while we also use escalators and lifts instead of stairs when we reach our destinations.

Appetite is a complex process controlled by several neural, humoral and psychological factors. It can be argued that in the past there has never been an evolutionary advantage in weight loss and as such we have evolved to consume as much food as possible whenever we can. A powerful drive to eat is induced by the homeostatic system regulating energy balance, especially after weight loss. Other basic drives include breathing and quenching one's thirst. Although it is possible for an individual to consciously hold his or her breath the compulsion to take another breath quickly overcomes the best effort. Hunger is an equally potent drive, not as intense as breathing, but probably not dissimilar to the drive to drink when one is thirsty.

The appetite regulation systems have always been under intense selective pressures and a gene–environment interaction is thus likely. Hunter-gatherers had to face famines and could only rely on food being sporadically available. The thrifty gene hypothesis states that genes that increased energy stores and predisposed to obesity could have provided a survival advantage.

Non-surgical treatments: lifestyle, pharmacotherapy and behavioural changes

In general, results of intentional weight loss and weight maintenance following lifestyle changes have been disappointing. A multitude of studies have examined the benefits of a low-calorie diet, with or without exercise and/or behaviour therapy. Most of the studies reported a degree of weight loss, but these were predominantly short-term effects. However, studies reporting longer term follow-up data demonstrated that the excess weight invariably returned to similar or even higher levels. This is consistent with the theory that early humans who existed as hunter-gatherers experienced continuous cycles of feast and famine. This may have resulted in an evolutionary advantage to those that could in times of famine recognize and act upon the signal of hunger. A further advantage could possibly be gained by those also able during times of feast to replace all the weight loss and even increase weight above previous levels to allow some buffer for future times of famine. The inherited ability to regain weight may contribute to the "yo-yo dieting" pattern so commonly observed today.

The role of pharmacotherapy in achieving weight loss is becoming less controversial. Many clinicians still feel that obesity is a function of poor will power and patients should on these grounds not be considered for pharmacotherapy. However, the same argument was previously levelled at hypercholesterolaemia, and it was only after effective agents became available to treat this co-risk factor for cardiovascular disease that pharmacotherapy became more widely accepted. Pharmaceutical companies are investing heavily in drugs to target obesity. What has remained unclear is what part of this complex system that controls energy homeostasis should be targeted to achieve the best results. The remarkable redundancy within the central nervous system that has evolved to ensure prevention or correction of weight loss during starvation with the least detrimental influence on health has prevented many pharmacological agents making it to market.

Currently, only one agent is available. Orlistat, a lipase inhibitor, prevents up to 30% of the absorption of fat by the gastrointestinal system. The mechanism of weight loss is however not directly linked to the pharmacodynamics, but more to the side-effect profile when fatty foods are ingested while orlistat is being used. The resulting diarrhoea or oily leak is unpleasant enough to discourage the continuation of a high-fat diet. The patient, if well informed, will usually change to a lower fat and thus less energy-dense diet, with a resulting decrease in weight. Weight loss on orlistat therapy is not a universal phenomenon, because many perpetual dieters consume low-fat foods. However, the volume and calorific value of these meals still ensure an energy surplus. These patients tend not to do well on orlistat, because unpleasant side effects occur less often due to the reduced fat in their diet.

Drugs such as sibutramine and rimonabant were withdrawn secondary to side-effect profiles that included increased cardiovascular death in patients with some pre-existing risks and significant depression, respectively. Several drugs are currently in development, but the weight loss rarely exceeds 10%. Recently the FDA approved two new drugs Qsymia™ and Belviq™ which are currently undergoing clinical trials. Despite the initial setbacks pharmacotherapy is predicted to continue to show rapid growth as most lifestyle interventions have been shown to be ineffective if not undertaken in conjunction with pharmacotherapy.

Weight loss utilizing surgical interventions

Surgical interventions for weight loss – also referred to as bariatric surgery – have proven to be the most effective method for intentional weight loss and post weight loss maintenance. The rationale for the original interventions was predominantly based on either restricting the progression of food through the gastrointestinal system or causing some form of malabsorption or a combination of the two. Weight loss surgery is not a cosmetic procedure and does not involve the removal of adipose tissue. It has been shown that animals undergoing such procedures have a marked reduction in appetite, a result which has also been observed in humans. The two possible mechanisms causing the reduction in appetite include neural and humoral factors. Most likely, both factors have roles and this hypothesis for weight loss is becoming increasingly popular.

Before patients can be considered for surgery, traditional methods such as diet, exercise and pharmacological agents should have been tried. The indications for bariatric surgery, based on the US National Institutes of Health criteria, are shown in Box 28.1.

These eligibility criteria may need to be re-evaluated as there is strong evidence of the effectiveness of bariatric surgery in ameliorating obese comorbidities independent of body mass index (BMI). The International Diabetes Federation argued that in some high-risk populations, e.g. Southeast Asian, bariatric surgery should be offered at a lower BMI in order to treat diseases like type 2 diabetes.

Undoubtedly, for the correct group of patients, surgery leads to significantly greater, and sustained, weight loss than that achieved with non-surgical treatments. This leads to the resolution of, or significant improvement in, many weight-related diseases and conditions, which in turn leads to increasing a patient's life expectancy and significantly improving their

BOX 28.1 Eligibility criteria for bariatric surgery

- Body mass index (BMI) ≥ 35 kg/m^2 with obesity related comorbidities (such as diabetes, sleep apnoea or joint problems)
- BMI ≥40 kg/m^{2*}
- Have tried all other methods of losing weight (diets, exercise, medication) including 6 months of a medically supervised programme but not been able to sustain weight loss
- Have no specific medical or psychological reasons why they should not have this type of surgery
- Are fit enough to undergo an anaesthetic and surgery
- Understand the need for long-term follow-up

* In the UK, The National Institute for Health and Clinical Excellence now recommends all those with a BMI ≥50 to be considered directly for surgery without the need for a prior 6 month medically supervised weight loss.

quality of life. There have been many high-quality studies in the literature supporting the above: the Swedish Obese Subjects (SOS) study; Sjöström *et al.*, Christou *et al.*, Adams *et al.* and Buchwald *et al.*

As a consequence of the effectiveness of weight loss surgery, there have been large increases in this field of surgery worldwide. In the USA, since 2006, the gastric bypass operation has been more prevalent than laparoscopic cholecystectomy. In the UK, recent data from the National Bariatric Surgery Registry (NBSR) and Hospital Episode Statistics (HES) data also document a 10-fold increase in bariatric operations from 238 operations in 2000 to 2543 in 2007. Despite these increasing trends, only a very small proportion of obese patients are receiving surgery, mainly due to artificial constraints placed by purchasers and non-coverage by insurers. A widening gap exists between those who would benefit from surgery and the lucky few who receive it.

Brief history of weight loss surgery

Jaw wiring was first used in the mid-1970s and had the purpose of restricting the opening of the patient's mouth, thus making the consumption of a usual meal impossible. These patients could therefore only consume liquid meals by using a straw. This highly regimented protocol ensured dramatic weight loss as the liquid diet contained much reduced calories. This form of surgical intervention was accompanied by a behaviour modification programme that tried to teach the patients to follow a low-calorie diet after the removal of the jaw wires. The end results were however very disappointing, although all the patients lost significant amounts of weight while their jaw movement was restricted they invariably regained all the weight after the wires were removed.

The first account of abdominal surgery for massive obesity is by Henrikson in the late 1950s where a massive small bowel resection was performed, leaving a short bowel. This led others to perform bypasses of the small intestine. The jejunoileal bypass (JIB) induced a state of malabsorption by bypassing most of the intestines while keeping the stomach intact. Although the weight loss with the JIB was good, too many patients developed serious complications such as blind loop syndrome due to bacterial overgrowth, abdominal bloating, migratory arthralgias, urinary stones and, unless adequate protein was consumed, liver problems. There were also electrolyte imbalances and anal burning from diarrhoea. Consequently, many patients have required reversal of the procedure.

In order to perform an operation without the side effects of the JIB, in the mid-1960s Mason developed the gastric bypass. This was based on the weight loss observed among patients undergoing partial stomach removal for ulcers. Initially the operation was performed as a loop bypass with a much larger stomach. Because of bile reflux that occurred with the loop configuration, Griffen modified the operation and performed it as a Roux-en-Y with a limb of intestine connected to a stomach pouch which prevents the bile from entering the upper part of the stomach and oesophagus. Torres made a further modification to this – a vertical pouch on the lesser curvature of the stomach. The Roux-en-Y gastric bypass (RYGB) has undergone many modifications since. In 1994, Drs Wittgrove and Clark reported the first case series of laparoscopic RYGB (LRYGB). The laparoscopic technique applies itself effectively to RYGB and its popularity continues to increase primarily because it has fewer peri- and postoperative complications (in particular wound problems), a shorter hospital stay, and a more rapid recovery time than open surgery.

Around the same time as the bypass was being developed, Scopinaro in Italy developed the biliopancreatic diversion (BPD), which was designed to be a safer malabsorptive alternative to the JIB. This operation induces controlled malabsorption without many of the potential side effects caused by bacterial overgrowth associated with the JIB. This primarily malabsorptive operation only allows for absorption of carbohydrates and fats in the distal 50–70 cm of ileum. BPD has been reported to provide the highest long-term weight loss of any bariatric operation. However, patients need close long-term postoperative follow-up for protein, vitamin and mineral deficiency as these remain significant complications following surgery.

The duodenal switch (BPD-DS) was a modification of the BPD proposed by Hess to prevent stomal ulcers, increase the amount of gastric restriction, minimize the incidence of dumping syndrome and reduce the severity of protein-calorie malnutrition. Anatomically, the main difference between the DS and the BPD is the shape and size of the stomach – the malabsorptive component is essentially identical to that of the BPD. Instead of cutting the stomach horizontally and removing the lower half (such as with the BPD), the DS cuts the stomach vertically and leaves a tube of stomach (a sleeve gastrectomy) that empties into a very short (2–4 cm) segment of duodenum. The BPD-DS can be performed using the laparoscopic approach and remains a popular option in a few centres around the world; however, most bariatric units are concerned with the side effects of malabsorption (daily diarrhoea), coupled with the possible complications of protein malnutrition and metabolic bone disease and thus the BPD-DS only forms ≤1% of all bariatric operations performed worldwide.

The first part of the DS (laparoscopic sleeve gastrectomy) is now being performed widely as a sole initial operation in poor-risk patients, with the option to add the DS portion or RYGB as a second operation if there is insufficient weight loss or weight regain. A 2009 consensus meeting on the sleeve gastrectomy reports impressive results with this operation as weight loss and health benefits are in line with those seen after LRYGB. The sleeve gastrectomy is gaining in popularity for these very reasons, but some authors have reported a small proportion of patients regaining weight and requiring further surgery.

In search of a safer, simpler technique, Carey and Gomez designed the gastroplasty in the early 1970s as an alternative to the RYGB and the JIB. The gastroplasty was the first purely restrictive operation performed for the treatment of obesity. However, the small horizontal pouch enlarged as did the outlet. Mason in 1982 reported the vertical banded gastroplasty (VBG) in which a vertical pouch is fashioned along the lesser curve of the stomach with the outlet controlled by a non-dilatable band. The VBG is still being performed with various modifications including via the laparoscopic route. However, its popularity has waned due to frequent regain of weight in the long term resulting from either pouch enlargement or fistula development between the two partitioned segments of stomach.

Molina in the early 1980s developed gastric banding as a potential restrictive procedure. A band was placed high around the stomach, producing a tiny pouch. Subsequently, others developed an inflatable gastric band attached by tubing to a subcutaneous reservoir through which saline could be instilled or withdrawn via a needle in order to adjust its tightness around the stomach, resulting in attenuated hunger and hence a reduction in food intake. The laparoscopic adjustable gastric band (LAGB) remains a popular surgical option worldwide, its success being dependent upon regular band follow-up/adjustments.

In addition to the operative interventions described above, a number of non-surgical procedures have also been developed as a treatment for excess weight. In 1985, a procedure was developed that aims to restrict the food consumed by the placement of a space-occupying device within the gastric lumen deployed via a gastroscope – the intragastric balloon. More recently, the EndoBarrier gastrointestinal liner system is an endoscopically delivered device that offers an alternative. Other techniques using endoscopic devices to produce gastric restriction are being developed, as are different ways to access the peritoneal cavity to perform currently accepted operations (natural orifice transendolumenal surgery and single incision laparoscopic surgery).

Preparation for surgery

Unit experience and infrastructure

The laparoscopic approach is technically challenging and there is a definite learning curve seen for bariatric surgeons. Depending on the reported case series, the number of laparoscopic gastric bypasses performed before levelling of the learning curve ranges between 75 and 100. This is again different for each procedure, with proficiency reported after 50 cases for either a sleeve gastrectomy or a gastric band. Once the curve plateaus, there is an observed improvement in patient outcome with respect to complication rate.

It is essential that any unit offering bariatric surgery should have the correct infrastructure in place. This includes wide corridors, doors, correct beds, trolleys, chairs, wheelchairs and floor-mounted toilets in any area where a bariatric patient may be seen – outpatient, inpatient ward, radiology suite, intensive care, emergency room, etc. Furthermore, the operating room must be adequately equipped for the bariatric patient in terms of the correct operating table, optics and laparoscopic instruments.

Thus the costs of establishing an integrated bariatric programme can be quite expensive as bariatric hospital beds at 2010 prices can cost up to US$30 000 and operating tables up to US$60 000. Furthermore, investment in training healthcare professionals is essential, not only in order to have the right bariatric multidisciplinary team (MDT) but also to ensure that other hospital staff ranging from porters, receptionists and nurses show appropriate sensitivity and care towards the bariatric patient.

The role of the bariatric multidisciplinary team and the patient journey

The input from a psychiatrist, a dietician, a bariatric physician, a specialist nurse and an anaesthetist is vital to promote a good outcome for the patient. Dietician input both before and after surgery is highly valuable so that patients can be informed of the necessary changes in eating (both quantity and type of food) that need to be made. Furthermore, assessment by a psychiatrist helps ensure that those patients with pre-existing psychological comorbidities receive therapy to ensure optimal benefit from surgery. Similarly, those patients with drug addictions, active psychoses and personality disorders, which all represent poor compliance with the surgery and its aftercare, will be filtered out by the psychiatrist. Figure 28.1 illustrates the typical bariatric surgery patient journey from referrer to surgery and thereafter.

Good preoperative work-up prior to a general anaesthetic is crucial. The patient will often have many comorbidities, including diabetes, hypertension, mobility difficulties secondary to arthritis and obstructive sleep apnoea. The last one may be undiagnosed, and if it remains undetected the patient can have anaesthetic complications postoperatively, including respiratory failure. Immobile patients are at high risk of deep vein thrombosis (DVT) and may thus require preoperative inferior vena cava (IVC) filter insertion. Thus care and attention in optimizing patients before surgery will reduce and often eliminate the need for intensive unit care in the peri- and postoperative period as well as reduce postoperative complications.

Certain groups of patients are at higher risk for complications because of the high prevalence of comorbidities, at the same time these very patients may also be the ones who benefit most from interventions. The King's assessment criteria can be used for an objective preoperative assessment of patients (Table 28.1).

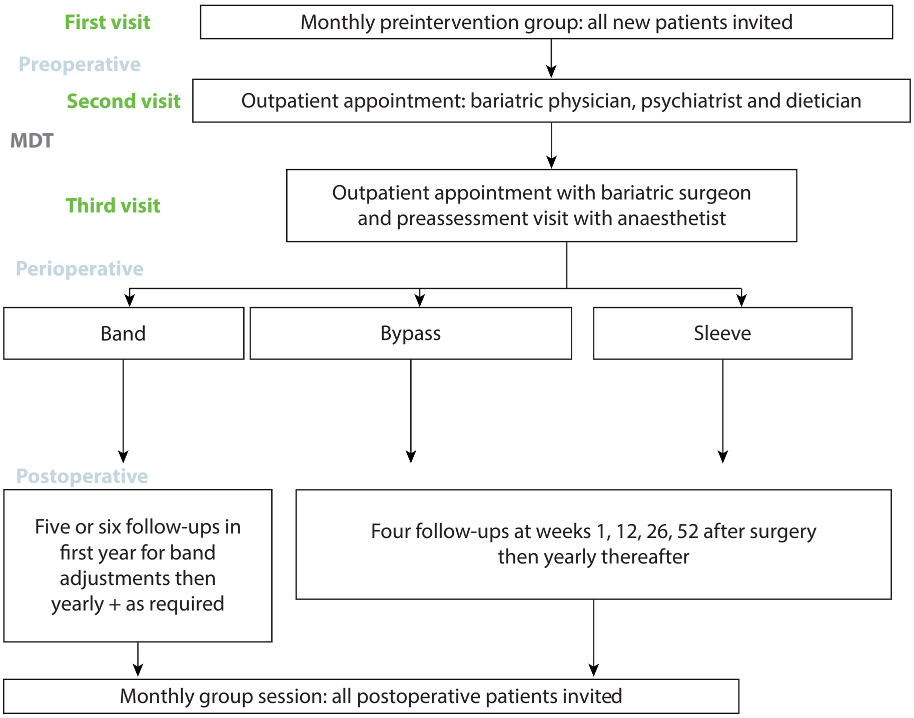
Before surgery

To optimize intraoperative conditions, the patient should undertake a specifically designed preoperative diet (approximately 900 kcal/day) for at least 2 weeks. This is in order to allow a fatty liver to shrink in size, hence permitting sufficient visualization and access to the left upper quadrant for the operation to take place.

Correct patient positioning is key for any bariatric procedure, not only in order for the surgeon to gain adequate access, but also for patient safety. Sometimes the operations can be prolonged, putting the patient at significant risk of developing intraoperative complications, including DVT, neuropraxia and rhabdomyolysis. An appropriate operating table with the facility of maximal head-up, with securing straps and footboards, is essential. Calf compression devices should be used during surgery to help prevent DVT, and similarly the use of subcutaneous heparin prior to incision is recommended for the same reason.

Choice of procedure

Traditionally patients who are 'volume eaters' have been recommended to undergo gastric banding whereas those with binge eating, snacking and sweet-eating tendencies have been selected for gastric bypass surgery. The sleeve gastrectomy was used as the first stage in a two-stage operation culminating



First visit
Monthly preintervention group: all new patients invited
Preoperative
Second visit
Outpatient appointment: bariatric physician, psychiatrist and dietician
MDT
Third visit
Outpatient appointment with bariatric surgeon and preassessment visit with anaesthetist
Perioperative
Band
Bypass
Sleeve
Postoperative
Five or six follow-ups in first year for band adjustments then yearly + as required
Four follow-ups at weeks 1, 12, 26, 52 after surgery then yearly thereafter
Monthly group session: all postoperative patients invited

Figure 28.1 A typical bariatric surgery patient pathway. MDT, multidisciplinary team.

Table 28.1 Modified King's criteria

	Stage 0	Stage 1	Stage 2	Stage 3
Airway	Normal	Snoring	Sleep apnoea require CPAP	Cor pulmonale
BMI (kg/m^2)	<30	30–35	35–50	>50
Cardiovascular	<25% risk	>25% risk	Heart disease	Heart failure
Diabetes	Normal	Impaired fasting glycaemia	Type 2 diabetes	Uncontrolled type 2 diabetes
Economic	Normal	Suffered discrimination	Unemployed due to obesity	Requires financial support
Functional	Can manage 3 flights of stairs	Manage 1 or 2 flights of stairs	Manage less than 1 flight of stairs or requires walking aids	Housebound
Gonadal	Normal	Irregular periods	PCOS/impotence	Infertility
Health status	Normal	Low mood or QoL	Moderate depression or poor QoL	Severe depression
Image	Normal	Does not like looking in mirror	Avoids mirrors/body image dysphoria	Severe eating disorder
Junction gastro-oesophagus	Normal	Heart burn	Oesophagitis	Barrett's oesophagus
Kidney	Normal	Proteinuria	GFR <60 mL/min	GFR <30 mL/min
Liver	Normal	Raised LFT/NAFLD	NASH	Liver failure

BMI, body mass index; CPAP, continuous positive airway pressure; GFR, glomerular filtration rate; LFT, liver function test; NAFLD, non-alcoholic fatty liver disease; NASH, non-alcoholic steatohepatitis; PCOS, polycystic ovarian syndrome; QoL, quality of life.

with a DS in the super-superobese (BMI >60). However such artificial divisions do not necessarily guarantee the best outcomes and probably what matters the most is that choice of surgical intervention should be made jointly by the patient and the clinician, taking into account the degree of obesity, comorbidities, the best available evidence on effectiveness and long-term effects, the facilities and equipment available, and the experience of the surgeon who will perform the operation. In fact, all bariatric procedures when used in motivated patients in a healthcare system able to provide regular follow-up will achieve their primary objective of improving health.

Patient safety

One of the most significant studies ever conducted on the safety of bariatric surgery is the Longitudinal Assessment of Bariatric Surgery study published in 2009. It followed 4776 patients who had bariatric surgery for the first time, evaluating complications and death rates within the first 30 days after surgery. Thirty-day mortality was low, ranging from no deaths in the laparoscopic adjustable gastric band group to 0.2% in the LRYGB group. Within 30 days of surgery, 4.1% of patients had developed at least one complication. The findings of this research very strongly reaffirm the safety of bariatric surgery.

Common types of weight loss surgery

Laparoscopic gastric band (Figure 28.2)

Surgical technique

A pneumoperitoneum is created in the standard technique and the liver left lobe retracted. Hiatus hernias should be looked for and repaired prior to proceeding with band placement. Traditionally the band was placed via a perigastric approach. The current standard of care is to use a pars flaccida approach, via a retrogastric tunnel between the pas flaccida medially and the angle of His laterally, since this produces a significantly decreased rate of band slippage. The band should be checked and prepped as per the manufacturer's instructions before placing it within the abdomen. The retrogastric tunnel is created by placing a Goldfinger at the right crus fat pad and then by rotating the tip through to the angle of His. If there is a large fat pad then this can be mobilized off the stomach. The band is then attached to the Goldfinger and gently pulled through and locked in position. To help prevent band slippage three or four anterior gastrogastric placation sutures are placed over the anterior aspect of the band. The catheter tubing that leads from the band is connected to a port reservoir. This is implanted in the subcutaneous layer of the abdominal wall over the rectus fascia, which allows adjustment of the band to the desired degree of constriction in the outpatient clinic. The band can be performed in 30–40 minutes as a day-case procedure.

Complications

The gastric band is the safest procedure in terms of operative mortality (<0.1%) but risk of further surgery for a band-related complication is in the range 5–10% over the following 10 years (Table 28.2)

Gastric or oesophageal perforation is extremely rare and is iatrogenic at the time of band implantation. Stoma obstruction can occur at any stage. In the early postoperative phase, it is the result of oedema or haematoma around the band, which often settles with time. Later on it is usually due to poor dietary habit and bolus obstruction. Gastric band erosion signifies slow migration of the band across the gastric wall thus making the band visible within the gastric lumen. The whole band may thus become internalized. The presentation is usually through weight regain and/or port infection. Gastric band slippage results from the stomach inferior to the band herniating above it, thus resulting in excessive stomach tissue inside the band, and to obstruction between the upper pouch and lower stomach. This condition usually presents acutely with vomiting. Oesophageal and gastric pouch dilation refers to symmetrical enlargement of the gastric pouch above the band, which may in turn lead to dilation and malfunction of the oesophagus (megaoesophagus). This entity is associated with maladaptive overeating and aggressive band adjustments. Symptoms include reflux and a decrease in satiety and restriction. However, it is not usually associated with obstruction. Patients may present with a sense of decreased restriction, requesting a band fill. However, this will exacerbate the problem. Pouch dilation can usually be treated non-operatively by temporarily defilling the band but sometimes needs band explantation.

Table 28.2 Gastric band complications

Band-related complication	Incidence	Port-related complication	Incidence
Slippage	4%	Port infection	5–10%
Erosion	1%	Port displacement	
Symmetric pouch or oesophageal dilation	5–10%	Needle-stick injury to tube	
Gastric perforation	0.1%		
Stoma obstruction	Variable		

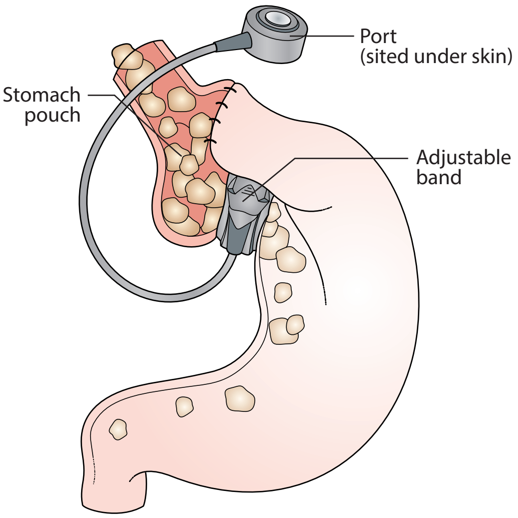


Figure 28.2 Gastric band.

Postulated mechanisms of action

Historically gastric banding was thought of as a restrictive technique; although that may have been the intention, it now appears after work by O'Brien *et al.* that restriction does not predict weight loss. Rather, the reduction in hunger that is a feature in 70–80% of patients with gastric bands predicts weight loss.

The mechanisms that cause the reduced hunger after gastric banding are not yet clear, but the hypotheses favoured at present include pressure on the vagus nerve fibres in the region where the band is situated. The traditional satiety gut hormones such as peptide YY (PYY), glucagon-like peptide 1 (GLP-1) and oxyntomodulin (OXM) do not appear to play a role after gastric banding. The changes in energy expenditure, ghrelin and leptin are also consistent with the weight loss observed after gastric banding. The improvements in glycaemic control depend on the weight loss and occur in a temporally consistent fashion to the changes in peripheral insulin sensitivity.

Results

Weight loss following gastric banding is variable and depends on the unit where it is carried out and patient follow-up. Some units in Australia report weight loss outcomes around 70% of excess weight, matching those seen with gastric bypass surgery. On average, however, most units will achieve around 50–55% excess weight loss (EWL) (roughly equivalent to around 20% total body weight loss) with the band.

Laparoscopic Roux-en-Y gastric bypass (Figure 28.3)

Surgical technique

The gastric bypass operation commences with formation of the vertical gastric pouch some 15–20 mL in volume. Dissection starts along the lesser curve, and the retrogastric adhesions and angle of His are freed. Sequential firings of an endostapler create a vertical gastric pouch. There has been much research into the size of the pouch. A retrospective study has suggested that smaller pouches may be associated with greater weight loss, although accurate measurement of pouch volume is difficult and prospective data are lacking. Most surgeons choose the transection point by measuring from the oesophagogastric junction as accurately as simply "eye-balling" the anatomy, or by counting vascular arcades. If too large, it can cause an increase in the rate of marginal ulceration and decreased weight loss.

In order to create the Roux-en-Y bypass, first the jejunum is divided at a point typically 30–40 cm distal to the ligament of Treitz. The distal segment is then moved cephalad to form the alimentary or Roux limb, and is surgically connected to the gastric pouch. This segment can be brought either ante- or retrocolic, and ante- or retrogastric, and there are different techniques in use for the formation of the gastrojejunostomy (handsewn, linear stapled or circular stapled). Benefits of the antegastric route include the relative increased ease of accessing the anastomosis and re-examining it if necessary at subsequent surgery, particularly in revision or relook surgery since it is not hidden underneath the stomach. Following creation of the gastrojejunostomy, most surgeons check for a leak intraoperatively using either methylene blue dye or oxygen through an orogastric (OG) tube with the anastomosis submerged under saline. A leak is thus ruled out in the absence of bubbling or blue dye. The proximal bowel segment, also called the biliopancreatic limb, is usually connected to the alimentary limb 75–150 cm distal to the gastrojejunostomy.

Several authors have addressed the issue of alimentary limb length during RYGB. For patients with a BMI of 50 kg/m^2 or less, there is no proven benefit for alimentary limbs longer than 150 cm. Other studies examining the use of alimentary limbs longer than 250 cm for patients with a BMI greater than 50 kg/m^2 have found improved weight loss over standard RYGB, but if greater than 300 cm there is increased nutritional deficiencies and need for reoperation.

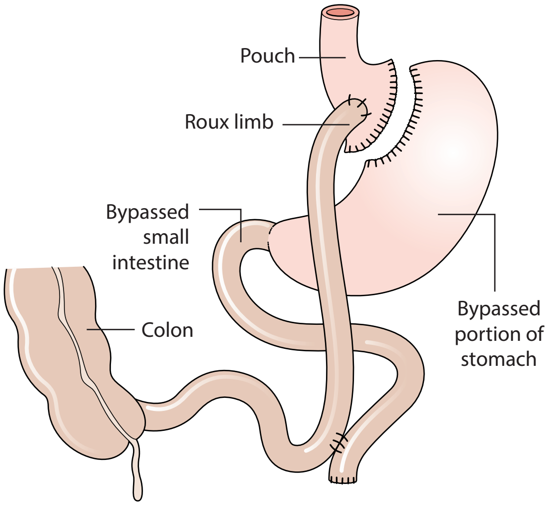

Figure 28.3 Roux-en-Y gastric bypass

One of the consequences of performing a RYGB is the creation of mesenteric defects in the transverse mesocolon (if retrocolic Roux limb) or jejunojejunostomy or through Petersen's defect. The latter defect is between the mesentery of the Roux limb and the transverse mesocolon. Internal hernias are more commonly observed in the laparoscopic RYGB than open, postulated to be a result of the fewer adhesions found in the laparoscopic technique. Closure of these defects at the primary operation is not performed universally by all surgeons, but overall is recommended by most surgeons.

The gastric bypass can typically be performed in 60–90 minutes with a 2 day stay in hospital.

Complications

These can be classified into general complications from bariatric surgery (which may also be seen with all bariatric operations) and more specific ones related to the bypass.

General complications include venous thromboembolic phenomena such as DVT (1%) and pulmonary embolism (0.1%) can be fatal (the International Bariatric Surgery Registry notes this as the most frequent cause of mortality following bariatric surgery) and all efforts are made to prevent these by using subcutaneous heparin peri- and postoperatively, calf compression devices, early mobilization post surgery and, where necessary, a low threshold for placing an IVC filter prior to surgery. Nutritional complications following surgery are unlikely as long as patients are compliant with their intake of multivitamin and mineral supplements. Patients should be followed up yearly and undergo blood tests to screen for micronutrient deficiencies, in particular iron, calcium, vitamin B_{12} and vitamin D deficiency (this may have been present prior to surgery). Other rare findings include vitamins A, B_1 and C, and selenium and copper deficiencies. Subsequent to rapid weight loss, bariatric surgery patients are at a higher risk of developing gallstones and may present with acute cholecystitis, biliary colic, choledocholithiasis and gallstone pancreatitis.

Specific complications related to the laparoscopic gastric bypass include gastrointestinal tract obstruction. This can occur at the gastrojejunostomy from a postoperative stricture (1%) or food bolus obstruction. More distally, small bowel obstruction (SBO) may be related to internal hernia formation (1–2%) where small bowel becomes trapped within iatrogenic gaps in the mesentery of the small bowel or transverse colon (retrocolic LRYGB). A further complication of the retrocolic LRYGB is Roux limb obstruction caused by narrowing within the transverse mesocolic defect. This tends to present earlier than internal herniation and is usually caused by cicatrix formation and extrinsic circumferential compression of the Roux limb. Other possible causes of SBO in this population include intussusception; adhesions; port site hernias; and obstruction at the jejunojejunostomy from kinking, stricture, or blood clot.

Gastric remnant distention can occur acutely or chronically and may present in the early postoperative period or years after surgery from obstruction of the biliopancreatic limb or common channel. Patients are usually in distress and have epigastric pain, nausea and tachycardia. In addition to leucocytosis, patients with an obstruction distal to the second portion of the duodenum may have elevated liver function test results and pancreatic enzymes from high duodenal pressure.

Marginal ulcers may develop at any stage after surgery and may occur in up to 10% of patients. The aetiology is multifactorial and may be related to one or more of the following: gastric acid; tobacco; non-steroidal anti-inflammatory drugs; *Helicobacter pylori*; gastro-gastro fistula; anastomotic tension and/or ischaemia, foreign body (suture) and large pouch size. Patients with ulcer perforation typically experience acute, severe epigastric pain and present with tachycardia, fever, leucocytosis and free air on plain radiographs or CT studies.

In the early phase following surgery bleeding (1–2%) and leaks (1–2%) at any of the staple lines or anastomoses may occur and require urgent reoperation. Delay in the treatment of a leak may result in severe sepsis and death. The presentation of a leak in the bariatric patient may be subtle with few symptoms other than just feeling 'unwell' and a mild tachycardia. Hence the bariatric surgeon must have high vigilance and a low threshold for re-exploration. Generally speaking, acute leaks in sick patients need relaparoscopy/laparotomy, washout and drainage. Late leaks in well patients may be manageable with conservative treatment using antibiotics, percutaneous drainage and stents.

Postulated mechanisms of action

The majority of modern Roux-en-Y gastric bypass techniques do not result in any calorie malabsorption or restriction of food through the gastric pouch. The operation can be viewed as having at least five components which may contribute to the mechanisms resulting in weight loss. These components include the small pouch, the bypass of the remnant stomach and first part of the small bowel, the undiluted bile flow in the first part of the small bowel, the early contact of the mid-jejunum with food and the disruption of the small vagal fibres when the stomach pouch is separated from the remnant stomach.

The mechanisms most prominent after the gastric bypass include the early satiety, reduction in calorie intake, the possible increase in energy expenditure and the changes in food preference from high-fat high-sugar foods to lower fat and low-sugar foods. Aversion or avoidance of sugary foods may seen subsequent to be 'dumping syndrome', which some patients experience after gastric bypass surgery.

The role of the satiety gut hormones PYY, GLP-1 and OXM has received prominence over the last few years, but the increasing focus on the role of bile acids, the neuronal signals generated by the altered anatomy and changes in gut microbiome may yield new insights. The improvements in glycaemic control after gastric bypass appear to be due to the increased insulin secretion as driven by the enhanced incretin responses, the improved insulin sensitivity, which includes both the early changes in hepatic insulin sensitivity and the later changes in peripheral insulin sensitivity as well as the change to a low glycaemic index diet.

Results

Weight loss following LRYGB is rapid in the first 6 months; thereafter, it plateaus and is 70–75% EWL (roughly equivalent to around 30% total body weight loss).

Laparoscopic sleeve gastrectomy (Figure 28.4)

Surgical technique

Following creation of a pneumoperitoneum, the operation starts by entering the lesser sac, then the gastrocolic and gastrosplenic ligaments are divided using an energy device. The lateral attachments of the stomach are divided along its greater curve. The new stomach can be sized around a bougie, or OG tube, the size of which varies between 32 and 44 French gauge. There is some evidence that smaller sized tubes (32–34 Fr) achieve greater weight loss. Formation of the sleeve usually starts 2–10 cm proximal to the prepyloric vein of Mayo. It is currently under debate whether sparing or resecting part of the antrum has an effect on weight loss. The endostapler is fired once via the right port, usually with a larger green or black cartridge, because of the thick-walled gastric antrum. The remaining stapler reloads (purple or gold) are placed from the left port. As the stomach is divided in a sleeve gastrectomy, the greater curve specimen to be removed assumes a diamond shape with a large round central portion tapering to a point at its upper and lower extent. Extraction of the gastrectomy specimen is through one of the laparoscopic ports, which may require gentle widening.

Some surgeons oversew the staple line or use fibrin glue or omentum to help prevent against haemorrhage or leak. Other surgeons use buttressing materials at the time of firing the endostapler. A variety of such materials are available and include: bovine pericardium (Peri-Strips Dry; Synovis Life Technologies, Inc.) and polyglycolic acid copolymer (SeamGuard; W.L.Gore & Associates, Inc.)

The laparoscopic sleeve gastrectomy can be performed in 45 minutes with a 1 day stay.

Complications

Historically the sleeve gastrectomy was used in high-risk patients as the first stage of a two-stage BDP-DS. This high-risk group, characterized by the accepted high-risk factors, including BMI ≥60 kg/m^2, demonstrated a notably low rate of complications including 1% for staple-line leakage and 2% for bleeding

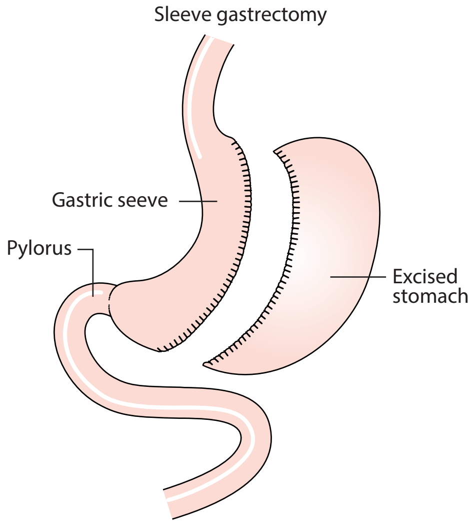

Figure 28.4 Sleeve gastrectomy.

and mortality within 30 days occurring in only 0.2%. With refinement of the sleeve gastrectomy technique as a primary procedure (including the use of staple line reinforcements) it is likely these complication rates will be further reduced.

Similar to other bariatric procedures, long-term nutritional surveillance is recommended especially as long-term postoperative nutritional complications may occur secondary to the extensive gastric resection by decreasing the absorption of some vitamins and nutrients, such as vitamin B_{12} and iron.

Postulated mechanisms of action

The mechanisms by which sleeve gastrectomy work are receiving major interest at present and may help revise many of the dogmas that currently prevail in bariatric surgery. The sleeve was specifically designed to cause restriction, but recent data show no restriction of food through the pylorus. Moreover, rodents with sleeve gastrectomy retain the ability to increase their food intake above levels of sham-operated animals if they are placed in a state where their hunger signals are activated. The satiety gut hormone responses of PYY and GLP-1 are similar to those of a gastric bypass. Changes in food preferences and energy expenditure may be less pronounced than after gastric bypass, but this has not been formally tested. Improved glycaemic control appears to be due to increased insulin secretion, although to a lesser extent than after gastric bypass. Insulin sensitivity also increases, but the time course appears more consistent with peripheral insulin sensitivity improvements related to weight loss than the early hepatic insulin sensitivity changes seen after gastric bypass.

Finally, the role of the pylorus after sleeve gastrectomy requires further study, as a known effect of the satiety gut hormones are to close the pylorus, and it is possible that once calorie intake has reached a certain threshold the pylorus will be closed prematurely resulting in a sudden feeling of fullness. Patients quickly learn not to continue eating once this has occurred as the side effect of vomiting may result.

Results

Weight loss following sleeve gastrectomy has been noted to be in the range of 60–70% EWL (roughly equivalent to around 25% total body weight loss) 1 year after surgery. The main problem is a deficiency of long-term follow-up data in the literature to confirm the effectiveness of this operation as a stand-alone intervention at 5 years or more.

Biliopancreatic diversion and duodenal switch (Figure 28.5)

Surgical technique

Both operations can be performed laparoscopically but take longer due to their technical complexity. Furthermore, interest is waning away from them due to (1) increased risk of serious complications, (2) need for close long-term follow-up to monitor for protein calorie malnutrition and bone mineral disease and (3) loose smelly stools from fat or bile acid malabsorption which may occur 2–4 times/day.

Complications

Table 28.3 lists the complications associated with the BPD and BPD-DS.

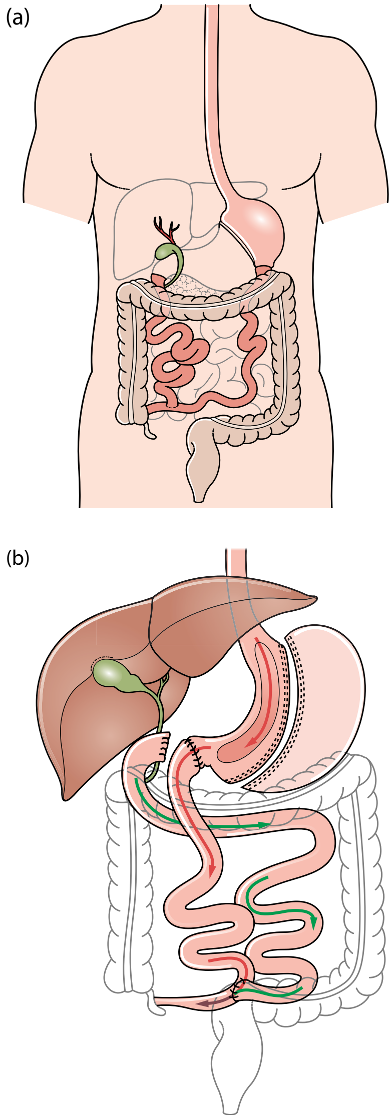

Figure 28.5 (a) Biliopancreatic diversion and (b) duodenal switch.

Postulated mechanisms of action

Calorie malabsorption is a feature of BPD and BPD-DS, but often the calorie loss in the faeces does not adequately explain the reduction in weight. It should however be noted that some patients have a very large increase in food intake after BPD and this may be secondary to the calorie malabsorption where the patient tries to compensate for the calorie loss by increasing the calories consumed.

The usual findings after BPD or BPD-DS are however a reduction in calorie intake and an increase in energy expenditure. The changes in food preference are less well documented. The improvements in glycaemic control appear to be primarily due to the improvements in insulin sensitivity. The BPD is the only procedure studied thus far that reduces peripheral insulin sensitivity early. This may be due to the reduction in intramuscular lipid content. Understanding the role of bile acids in the much increased biliopancreatic limb may help elucidate the mechanisms of the BPD and BPD-DS.

Table 28.3 Complications associated with BPD and BPD-DS

Complication	Incidence (%)
Protein malnutrition	12
Anaemia	35
Incisional hernia (if performed open)	10
Stomal ulcer (less with BPS-DS)	5
Bone demineralization	15
Vitamin deficiency (A, D, E, K, and β-carotene)	30
Dumping syndrome (less with BPD-DS)	

BPD, biliopancreatic diversion; DS duodenal switch.
Source: American Society of Bariatric Physicians.

Results

The BPD and BPD-DS offer the least reduction in eating capacity with the most weight loss with 80–90% EWL (equivalent to 40% total body weight loss) as well as the highest rates of resolution of the metabolic syndrome. However, because of the complex nature of the surgeries, risk of complications and many side effects, these operations remain less popular with most bariatric surgeons.

A summary of the common bariatric operations in current clinical usage is shown in Table 28.4.

Other bariatric interventions

Intragastric balloon

This is implanted under endoscopic guidance and fills the stomach and thus reduces the potential volume for food in the stomach. The presence of the balloon will cause severe vomiting if too much food is consumed. The device is temporary and needs to be removed after 6 months. Although indicated as a primary treatment for those who are overweight (BMI >27) and those suffering from obesity, this procedure may also be used to prepare extremely obese patients for other forms of weight-reducing surgery. The average weight loss seen with the balloon is around 15–20 kg.

Endoluminal duodenal sleeve

This endoscopically implanted device shields the duodenum and upper jejunum from contact with chyme, thereby mimicking the foregut bypass effect of a gastric bypass procedure without altering the patient’s anatomy. Pancreatic and biliary secretions pass along the outside of the devices and then mix with chyme in the upper jejunum. The device is temporary and needs to be removed after 6–12 months. Based on animal experiments and clinical observations, this device may provide a useful non-surgical intervention for treating type 2 diabetes with an added benefit of providing some weight loss. This device is currently under investigation in industry-sponsored clinical trials.

Gastric pacing and VBloc

Gastric pacing (gastric electrical stimulation) is being experimented with following the work of Cigaina. It consists of a small battery-powered ‘pacemaker’ implanted under the skin beneath the ribs. This device is then attached to two electrodes positioned in the muscle of the anterior gastric wall at the lesser curvature (via laparoscopic surgery). Although the mechanism of action remains unknown, the application of a small electrical impulse to the stomach is thought to induce early satiety and reduce appetite. Another system known as VBloc therapy involves placing the electrodes around the vagal trunks at the level of the gastro-oesophageal junction. Results using these techniques have only demonstrated limited weight loss. Further development of this technology is felt necessary before the device is accepted as bona fide treatment for excess weight.

Clinical effectiveness of surgical intervention

For simplicity, these can be categorised according to the ‘A–O’ Kings criteria.

Airway and apnoea

Severe obesity can be associated with significant respiratory problems. The most important among them are obstructive sleep apnoea and asthma. Among severely obese patients presenting

Table 28.4 Summary of common bariatric operations

	Gastric band	Gastric bypass	Sleeve gastrectomy
Type of surgery	Gastric	Combined	Gastric
Surgical duration	30–45 minutes	60–90 minutes	45–60 minutes
Hospital stay	Day case	2 days	1–2 days
Weight loss (1 year)	20%	30%	25%
Mortality rate	0.01%	0.16%	0.02%
Advantages	Reversible and adjustable Low early operative complication rate	Quick, dramatic weight loss Long clinical track record Good for sweet eaters as ‘dumping’ discourages high-sugar foods	No intestinal bypass Good weight loss
Disadvantages	Use of prosthetic device increases risk of malfunction or infection Risk of band slippage or erosion means 10% reoperation rate long term Regular follow-up – critical for weight loss	Early complications (2%) may be serious 1% long-term risk of bowel obstruction	Early complications (1%) may be serious No long-term data

for interventions such as bariatric surgery more than 70% meet the criteria for obstructive sleep apnoea.

In 2004, a systematic review and meta-analysis reported improvements of sleep apnoea in 85% and resolution in 83% after bariatric surgery. Numerous studies demonstrate an association between obesity and asthma. BMI has a strong, independent and positive relation with asthma. Severely obese patients with asthma experience resolution or improvement after bariatric surgery. A large single-centre study found that 26% of severely obese patients suffer from asthma preoperatively and the resolution after RYGB was 66%. Several groups have reported major reduction in asthma severity after bariatric surgery-induced weight loss.

Body mass index and waist circumference

The average weight loss after medical interventions is between 5 and 10 kg, and for bariatric surgery it is 20–40 kg. Maintenance of weight loss after medical interventions is however poor, while in the SOS study the mean weight loss following surgery over 10 years was 19.9 kg. Mean weight loss is maximal after 1–2 years, after which weight slowly increases for a decade before it stabilizes. After a period of 15 years in the SOS study, patients who had undergone laparoscopic gastric banding and Roux-en-Y gastric bypass had lost 13% and 27% of their total body weight respectively.

Few randomized controlled trials have compared weight loss between surgical procedures. In one of them sleeve gastrectomy seems to achieve the same weight loss as RYGB at 1 year follow-up. Furthermore, Himpens *et al.* compared laparoscopic sleeve gastrectomy and LAGB at 1 and 3 years' follow-up and found that sleeve gastrectomy has a significantly greater weight loss and reduction in BMI. On the other hand, Angrisani *et al.* showed in a randomized controlled trial that the mean weight was significantly better in the LRYGB than the LAGB after 5 years of follow-up.

Cardiovascular disease

Severe obesity increases the frequency and the severity of the metabolic syndrome, which is the major risk factor for cardiovascular disease. Its prevalence in obese patients was nearly 10-fold higher than in non-obese patients. The definition of metabolic syndrome includes the coexistence of any three of the following five features: central obesity, high serum triglyceride levels, low serum high-density lipoprotein cholesterol levels, hypertension and elevated fasting blood glucose levels. The different components of the metabolic syndrome can be addressed with effective pharmacological treatments, but it appears that reduction of visceral adiposity reduces all the components simultaneously. Buchwald reported a 62% improvement of hypertension, 70% of hyperlipidaemia and 86% resolution of diabetes in obese patients undergoing surgery. Interestingly Ahmed *et al.* (2009) have observed an early reduction in blood pressure just a week following LRYGB, suggesting alternative weight independent mechanisms for the change observed.

Bariatric surgery also delays the progression of atherosclerotic disease. In a controlled 4 year interventional study of carotid artery atherosclerosis, obese patients treated with surgery had a threefold lower rate of progression than controls. It is noteworthy that two large retrospective studies show reduced long-term mortality of cardiovascular diseases. Adams found that the cause-specific mortality in the surgery group decreased by 56% for coronary artery disease and Christou reports that the risk of cardiovascular disease decreased by 72%. Moreover, the severity and the duration of obesity are associated with changes in cardiac structure and function. The most frequent abnormalities are the increased cardiac mass, left ventricular hypertrophy and abnormal measures of diastolic left ventricular function. Bariatric surgery has been demonstrated as a successful modality to improve left ventricular hypertrophy as well as systolic and diastolic performance.

Diabetes

Obesity and type 2 diabetes mellitus are likely to be some of the greatest public health problems in the world. There is a strong relationship between the two and the term 'diabesity' has been coined to suggest an overlap of the problems. Approximately half of those diagnosed with type 2 diabetes mellitus are obese, and 20–30% of those who receive bariatric surgery are diabetic.

Medical advances have delivered significant improvements in glycaemic control and the reduction in micro- and macrovascular disease. Remission of type 2 diabetes remains difficult to achieve without the use of bariatric surgery. A recent meta-analysis demonstrates that bariatric surgery has impressive results in the treatment of diabetes, with 78% of diabetic patients demonstrating complete remission and 86% an improvement or remission of diabetes after bariatric surgery. Further randomized controlled trial data from the STAMPEDE trial and Mingrone *et al.* add further weight to the evidence supporting surgery as a treatment option for type 2 diabetes. Regarding the effectiveness of each procedure, diabetes remission is greatest for patients undergoing BPD/DS, followed by gastric bypass, and least for gastric banding. In a randomized controlled trial, Dixon and colleagues compared the effectiveness of laparoscopic gastric banding and conventional therapy in remission of type 2 diabetes mellitus at 2 year follow-up and found that it was significantly higher (73%) in the LAGB group than in the conventional group (13%). Generally, bypass procedures produce the highest and most rapid rates of type 2 diabetes mellitus remission; this is thought to occur by a weight loss-independent mechanism that may involve the role of gut hormones through the so-called enteroinsular axis. Adams in a large cohort study described a remarkable 92% decrease in diabetes-related deaths after RYGB.

Economic complications

The major economic complications for obese patients are unemployment, reduced productivity and the cost of care due to the comorbidities which are related to obesity. The social stigma associated with being overweight may limit a person's ability to get a job. The majority of studies investigating occupational status showed an increase in employment after surgery. Productivity has also been shown to increase significantly after bariatric surgery, with fewer days on sick leave. The SOS trial showed that the number of days lost due to sick leave before the operation was twice as high and disability pension twice as frequent as in the general Swedish population. During the first year after treatment, the surgically treated group had 35% more days of sick leave than the controls, but significantly fewer days during the second and third year. During years 4 and 5, the difference in sick leave between groups was not significant.

In a study on the economic impact of bariatric surgery, the costs of open surgery are fully recovered after 4 years, and for laparoscopic bariatric surgery are fully recovered after 2 years. The cost reductions observed in this analysis mirror the comorbidity reductions in diseases associated with obesity in terms of prescription drug use, hospital visits and physician visits.

Functional (physical functioning)

Severely obese individuals experience significant impairment in activities of daily living such as walking, climbing stairs and bathing. These are reported to be the most distressing aspects of their obesity. Furthermore, obese and overweight individuals face an increased risk of musculoskeletal pain and osteoarthritis. O'Brien in a randomized clinical trial found that physical functioning scores of obese patients who underwent LAGB improved significantly more than medically treated patients. Moreover, the SOS study reports that patients who underwent bariatric surgery reported significant improvement (or resolution) in types of 'work-restricting' pain in the neck, back, hips, knees and ankles. In a prospective study McGoey found that after a mean surgical weight loss of 44 kg the prevalence of back pain decreased from 62% to 11%, hip pain from 11% to 2%, knee pain from 57% to 14%, ankle pain from 34% to 2% and foot pain from 21% to 1%.

Gonadal

Obesity is associated with infertility. In a large, prospective, multicentre study, 42% of women prior to undergoing bariatric surgery experienced subfertility, but 61% had a live birth after surgery. The mechanisms contributing to subfertility in this cohort may include androgen excess, insulin resistance, and hyperinsulinism. Numerous studies found evidence of improvement in fertility after bariatric surgery via the normalization of hormones and menstrual cycles and the reduction of PCOS. PCOS is a syndrome characterized by infertility, menstrual dysfunction, hyperandrogenaemia and hyperinsulinaemia. In the LABS study PCOS was diagnosed in 13% of women undergoing bariatric surgery, a rate significantly higher than that of the general population. In a prospective study of 12 women with PCOS after bariatric surgery all had improvements in hirsutism, hyperandrogenaemia, insulin resistance and restoration of regular menstrual cycles and/or ovulation. In another retrospective study of 24 women who had PCOS and gastric bypass, all had complete resolution of their menstrual irregularity and those who wanted to fall pregnant were able to do so without the need for clomiphene, while 75% had marked improvement in a hirsutism score.

A number of studies have shown that maternal obesity introduces multiple risks for the mother and the fetus during pregnancy. According to the American College of Obstetrics and Gynecology, all bariatric surgery patients are advised to delay pregnancy during the rapid weight loss phase within the first 12–18 months postoperatively. A systematic review of maternal and neonatal complications suggests that the risk for maternal complications, such as gestational diabetes and pre-eclampsia, may be lower following surgically induced weight loss than the risk in obese women and may approach non-obese population rates. Similarly, neonatal complications, such as premature delivery and low birth weight, may be lower in pregnancies following bariatric surgery.

Obesity is also associated with high risk of sexual dysfunction. Many patients present for bariatric surgery with the expectation that weight loss will improve their sexual relations with their partner, and most patients indicate a significant improvement and a more satisfying sexual life postoperatively.

Health status

Previous research has demonstrated that 25–30% of patients had marked clinical symptoms of depression before surgery. The SOS provides the best available evaluation of changes in overall mood, depression and anxiety after bariatric surgery. Poor general health perceptions have frequently been associated with limitations in functional ability, physical and mental symptoms and a number of medical diagnoses. In the SOS study, health perceptions improved by 11% after 10 years. The significant improvement from baseline to 10 year follow-up is in line with the positive long-term effects of weight reduction but was significantly lower than the population norm.

Overall, significant improvements were observed in the surgical group during the first year after bariatric operation. However, the effect on overall mood after 10 years was positive in patients with weight losses of 10% or more, whereas no improvement was observed in patients who lost less than 10% of their initial weight. The depression scores decreased to about 27% at 10 year follow-up. Depression was improved at 10 year follow-up, but the prevalence was still higher than the population norm. A substantial short-term reduction of anxiety symptoms (23%) was seen in the surgical group 10 years after surgery.

Severe obesity is associated with multiple forms of negative health impact that affect quality of life. The SOS study demonstrated that long-lasting weight reduction after bariatric surgery has a general longstanding positive outcome on health-related quality of life. In another recent comparison of gastric bypass surgery with severely obese patients who did not undergo surgery, gastric bypass led to improved health-related quality of life.

Image

Commonly, overweight and obese individuals suffer from body image dysphoria. Several studies have reported the association between weight loss after bariatric surgery and improvement in body image. Adami and colleagues reported that, 3 years after the operation, the scores of patients on the body image dissatisfaction subscale dramatically improved and were similar to the scores observed in normal weight individuals. The great majority of studies indicated a considerable improvement of self-esteem after surgery.

Eating disorders are common in patients undergoing bariatric surgery. Approximately 10–25% of patients meet the criteria for binge-eating disorder (BED) and the prevalence of night-eating syndrome (NES) is between 5% and 20%. BED involves repeated uncontrolled episodes during which objectively large amounts of food are consumed, in association with marked emotional disturbance. Several studies have investigated the relationship between the presence of BED before surgery and the postoperative weight loss, but the results are contradictory. There is evidence that RYGB may improve eating disordered behaviour. Hsu and colleagues report that none of the patients who had BED preoperatively reported BED after RYGB. In another study of LAGB, preoperative BED, uncontrolled eating and NES occurred in 14%, 31% and 17.1% of subjects, respectively. These eating disorders were reduced after surgery to 3.1%, 22.5% and 7.8%, respectively. Having active BED when having surgery may be a poor prognostic feature and hence treatment should be considered before the operation.

Gastro-oesophageal junction

Gastro-oesophageal reflux disease (GORD) has been shown to have a strong association with BMI. Central adiposity may be the most important risk factor for the development of reflux and related complications such as Barrett's oesophagus and oesophageal adenocarcinoma. RYGB seems to be a beneficial surgical treatment for GORD in obese patients as the small stomach pouch reduces acid production and limits reflux. In a prospective study, GORD symptoms decreased in 94% of patients at 9 months postoperatively. Similarly in another study the resolution of GORD after RYGB was 87.6%. Frezza *et al.* examined prospectively the effect of RYGB surgery in 152 severely obese patients with chronic GORD. Approximately 80% of patients had GORD symptom resolution at 6 months follow-up. LAGB is another option for the treatment of obesity and GORD symptoms. Dixon *et al.* demonstrated resolution of all reflux symptoms in 76% and improvement in another 14% of patients undergoing LAGB.

Despite the proposed benefit of banding in reflux, other studies have shown contradictory results and worsening of reflux symptoms after LAGB. A recent systematic review revealed that although LAGB often leads to improvement or even resolution of reflux symptoms in the short term, worsening or newly developed reflux symptoms and oesophagitis were reported in a subset of patients when longer follow-up was available. Further well-designed studies with long follow-up are needed to establish the effect of banding on this disease.

Csendes reports that, in obese patients, the incidence of Barrett's oesophagitis preoperatively was 2%. After RYGB, symptoms of reflux disease, signs of erosive oesophagitis and peptic ulcer disease were no longer present. Additionally, Houghton in a study of five patients with Barrett's oesophagitis preoperatively reports complete or partial regression of Barrett's oesophagitis after RYGB in four of them and improvement in reflux symptoms in all.

Kidney

Obesity is associated with impaired renal parameters, obesity-related glomerulopathy and chronic kidney disease (CKD). Obese patients in the Framingham study who were initially free of CKD were likely to reduce their glomerular filtration rate (GFR) over time. In a study of 61 patients, renal parameters and renal function were markedly improved 24 months after bariatric surgery. The earliest marker of CKD risk is microalbuminuria and is associated with risks of progression to end-stage CKD. A recent meta-analysis found that weight loss is associated with decreased proteinuria and microalbuminuria. The literature is incomplete, but a case series describes improvements or stability of CKD and improved outcomes in renal transplant patients. In a retrospective study in 25 patients with chronic renal disease, 12 months after receiving bariatric surgery the mean GFR increased significantly compared with preoperatively.

Liver

Non-alcoholic fatty liver disease (NAFLD) includes a wide spectrum of liver disease from hepatic steatosis, non-alcoholic steatohepatitis (NASH), fibrosis and cirrhosis. In a review of obese patients undergoing bariatric surgery, the prevalence of steatosis was 91%, the prevalence of NASH was 37% and the prevalence of unexpected cirrhosis was 1.7%. Obesity and insulin resistance are considered to be the main causative factors of NAFLD. Several studies on severely obese patients with NAFLD have shown an improvement in liver disease after bariatric surgery. Dixon studied 36 severely obese patients with NAFLD who underwent LAGB, comparing liver biopsies at a mean 2 year follow-up and showing significant improvements in steatosis, fibrosis and necroinflammatory scores. In a meta-analysis on the effect of bariatric surgery on NAFLD, 92% of patients showed improvement or resolution of steatosis; for steatohepatitis the percentage was 81%, for fibrosis it was 65% and for complete resolution of NASH it was 69%.

Medication

Obesity and its comorbidities are associated with increased prescription drug use. In the SOS study, 52% of the obese individuals were taking medications compared with only 36% of the randomly selected reference population. The obese patients in this study were more often taking medication for cardiovascular disease, pain, psychiatric disorders, diabetes mellitus and asthma. In the SOS study, of the obese individuals in the surgical group taking any medications at baseline, 77% were still taking medications 6 years after the operation.

In RYGB, a large study reports that the average use of medications reduced from 4.4 per patient preoperatively to 1.3 after the procedure. Similarly, in another study, the mean number of medications for the treatment of hypertension, hyperlipidaemia, GORD and type 2 diabetes mellitus in 77 patients decreased from 2.4 preoperatively to 0.2 medications per patient 12 months after RYGB.

Nutrition

Bariatric surgery is related to changes in eating behaviour. Olbers *et al.* showed in a randomized controlled trial that patients after RYGB have a decreased preference for sugary and fatty foods, whereas they increase their preference for vegetables. The SOS study also reports dramatic changes in eating behaviour in the surgical group 6 months after the operation and also at 2 year follow-up.

Other obese comorbidities

Cancer incidence is increased in obese individuals. A recent meta-analysis showed that high BMI is associated with an increased incidence of many types of cancers. Certain recent studies support that bariatric surgery is associated with a reduction in the overall cancer incidence. In the prospective SOS cohort study the number of first-time cancers after inclusion was lower in the surgery group than in the control group. Moreover, the SOS study concluded that bariatric surgery had a significant effect on cancer incidence in women but not in men.

In two retrospective cohort studies of obese patients treated with bariatric surgery there was also a reduction in cancer incidence in patients who underwent bariatric surgery compared with those who did not. Adams found that mortality in the surgery group decreased by 60% for cancer during a mean follow-up of 7.1 years and Christou, after a follow-up of 5 years, found that the post-bariatric surgery group have significantly fewer visits to the physician/hospital for 'all cancer' diagnosis than the non-operated, severely obese control group. There were only 2% reported bariatric surgery patients with cancer compared with 8.5% control subjects. A recent retrospective study focusing on breast and endometrial cancer incidence showed that bariatric surgery may decrease cancer development.

CHAPTER 29

Disorders of the small intestine and vermiform appendix

SIR ALFRED CUSCHIERI

Anatomy

The small intestine is divided into three anatomical portions: duodenum, jejunum and ileum. However, in surgery, the duodenum, which forms the first 25 cm, is considered with the stomach because of various pathologies which affect both organs, such as peptic ulceration. At postmortem the average length of the small intestine *in situ* is about 7 m, with a reported range of 4.3–10.3 m when the measurement is made along the antimesenteric border. These estimates have to be regarded as approximate and are certainly not exact in view of the distensibility of the small intestine, the flaccid state after death and indeed the method of measurement (usually by tape) used in these postmortem studies. The length of the intestine (less the duodenum) when measured along its attached or mesenteric border, is only 4.6 m.

The tone of the smooth muscle reduces the small bowel length considerably during life. Accurate assessment of intestinal length at operation is thus difficult owing to the changing state of the intestinal loops due to peristaltic activity, handling and exposure. In the adult, the length of the small bowel measured along its antimesenteric border and in the unstretched state after a preliminary laparotomy averages 3.5 m. After substantial resections of the small bowel, it is important to measure and record the extent of the residual small intestine in the operation, as this is more useful in subsequent management and prognosis than the extent of resected bowel.

Small bowel mesentery

The small bowel mesentery (SBM) is a fat-laden peritoneal reflection which attaches the jejunum and ileum to the posterior abdominal wall. This attachment, known as the root of the small bowel mesentery (RSBM) and measuring 15 cm, runs obliquely down from the ligament of Treitz to the ileocaecal region and overlies a bare area continuous with the anterior pararenal space of the retroperitoneum. The RSBM contains two major vessels, the superior mesenteric artery and vein (SMA, SMV), in addition to other important structures. Superiorly, the RSBM is continuous with the hepatoduodenal ligament around the SMV and portal vein. Anteriorly, it is continuous with the transverse mesocolon, and posterolaterally with the ascending and descending mesocolon and anterior pararenal space. The right gastrocolic trunk marks the junction between the transverse mesocolon and the RSBM. The inferior mesenteric vein joins the SMV or splenic vein on the left side of the RSBM.

The length (depth in the supine position) of the SBM is important surgically, especially in the creation of Roux-en-Y loops. It increases gradually from the duodenojejunal flexure (ligament of Treitz) and reaches its maximum at 1–1.25 m, where it measures 18–20 cm and then diminishes in length, such that at the mid-ileum it measures 12–13 cm and then shortens rapidly as it approaches the caecum. The lower part of the SBM forms a fold that can be easily palpated during surgery. It is a useful landmark for access to the fossa on the left side of the mesentery for irrigation in patients with generalized peritonitis.

Jejunum and ileum

The jejunum, which constitutes the proximal two-fifths, and is about 2.5 m long, for the most part occupies the umbilical and left iliac regions, whereas the ileum occupies chiefly the umbilical, hypogastric, right iliac and pelvic regions; the distal ileum tends to be situated in the right iliac fossa and pelvis. The terminal ileum usually lies in the pelvis, from which it ascends over the right psoas muscle and right iliac vessels to the right iliac fossa to open into the medial side of the caecum. There is no clear demarcation line between the jejunum and the ileum, but the proximal jejunum is thicker and more vascular than the ileum, has a darker colour with prominent plicae circulares and has an overall diameter of 4.0 cm. The circular folds of its mucous membrane are large and thickly set (thus palpable between finger and thumb as distinct from the ileum), and its villi are larger than in the ileum. The aggregated lymph nodules are almost absent in the upper jejunum, and are sparse, smaller and tend to be circular compared with the ileal Peyer's patches. The mesentery of the jejunum contains less fat and the mesenteric vasculature consists of prominent arteries and veins which join to form one or two arcades in the mesentery before giving rise to the terminal intestinal branches.

The ileum is narrower (average diameter 3.0–3.5 cm), thinner and less vascular than the jejunum. It possesses but few circular folds which are small (impalpable externally) and which disappear entirely in its terminal reaches. In contrast, the ileum contains larger and more numerous aggregated lymph nodules (Peyer's patches). The mesenteric vasculature of the ileum is more complex, with the vessels forming four or five levels of arcades before the origin of the terminal intestinal branches.

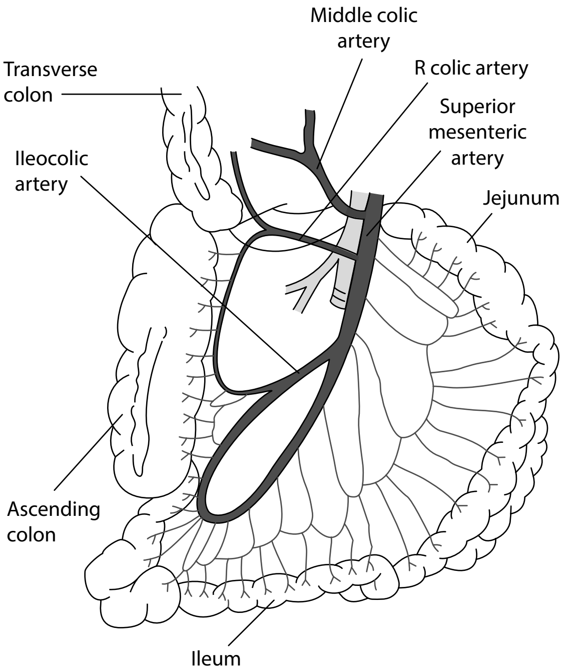

Figure 29.1 Superior mesenteric artery and vein.

Vascular supply

The whole of the small bowel is supplied by the SMA (Figure 29.1). An understanding of the anatomy of the mesenteric vascular arcades of the small intestine is essential for the safe execution of reconstructive procedures on the gastrointestinal tract involving small bowel segments, e.g. ileal pouch construction.

The intestinal branches of the SMA on reaching the attached border of the bowel run between the serous and muscular coats with frequent crossing over of the free border of the intestine, where they anastomose with other branches running around the opposite surface of the small bowel. These vessels give off numerous branches, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous layer from which minute vessels supply the glands and villi of the mucous membrane. The veins run a similar course and arrangement to the arteries. The lymphatics of the small intestine (lacteals) are arranged in two sets: those draining the mucous membrane and those of the muscular coat. The lymphatics of the intestinal villi form an intricate plexus in the mucous and submucous layer, where they are joined by the lymphatics from the lymph spaces at the bases of the solitary nodules. Thereafter they proceed as larger channels (lacteals) at the mesenteric border of the small intestine. The lymphatics of the muscular coat are situated between the two muscular coats, where they form a plexus, but throughout their course they communicate freely with the lymphatics from the mucous membrane, and ultimately empty in the lacteal vessels.

The arteriolar supply to the small bowel is of particular surgical interest. Each arteriole and accompanying venule supply and drain one-half of the circumference of the small intestine, and the vessels are distributed to alternate sides of the bowel wall in regular sequence (Figure 29.2). This arrangement forms the basis of intestinal lengthening operations in infants and children with short gut syndrome as the residual bowel can be split longitudinally, with each half retaining an adequate blood supply (see section Short gut syndrome).

Microanatomy

The small bowel mucosa is arranged in villi and crypts. The villi form finger-like projections measuring 0.5–1.5 mm in length (Figure 29.3a,b), with the crypts forming depressions below the surface in between the projecting villi. These are

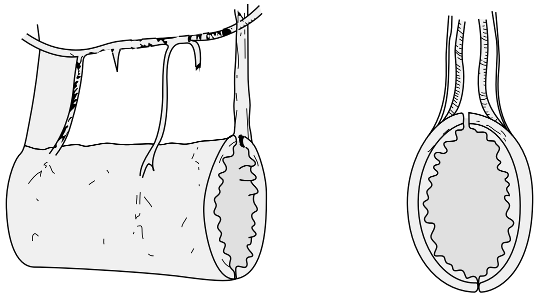

Figure 29.2 Diagrammatic representation of the distribution of the terminal branches of the mesenteric vessels to the small intestine. These are distributed to alternate sides of the gut.

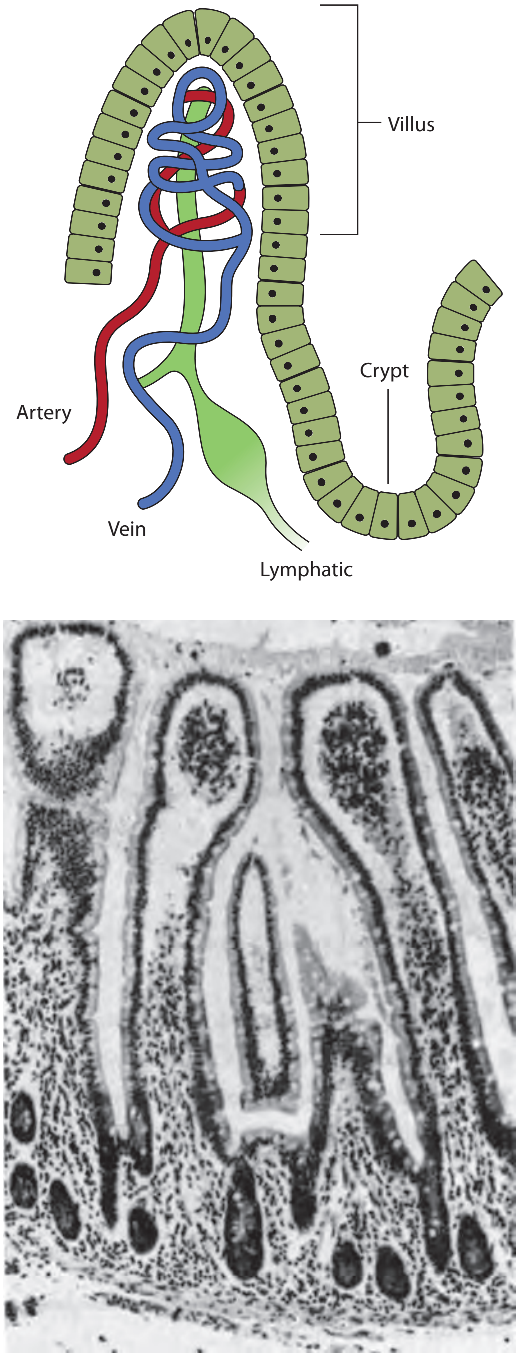

Figure 29.3 (a) Schematic anatomy of the small bowel villus and crypt. (b) Microphotograph showing normal appearance of jejunal mucosa.

covered by tall columnar mature absorptive cells (enterocytes) which have microvilli at their luminal surfaces (brush border). These enterocytes rest on a thin basal membrane (lamina propria), and their microvilli are kept lubricated by a surface mucus known as the glycocalyx, which separates the brush border from the intestinal contents. Goblet cells, found interspersed among the enterocytes, synthesize the mucinous glycoprotein essential for maintaining the glycocalyx. At their bases, the villi are surrounded by intestinal crypts (of Lieberkuhn) which are lined by young epithelial secreting cells. Stem cells are found at the base of the crypts. These are constantly dividing in order to replace the surface epithelium by a process of cell division and migration. The divisions of these stem cells produce new stem cells (which remain pluripotential) and other cells which are committed to differentiate along one of four lineages to become enterocytes, enteroendocrine, goblet and Paneth cells. The cells following the enterocyte lineage divide several more times as they migrate up the crypts. During this migration, they differentiate further into the mature absorptive cells that express all the transport proteins and enzymes characteristic of the mature enterocytes.

The other cells found in the crypts are goblet cells in the upper half, Paneth cells at the base and endocrine cells. The Paneth cells are pyramidal in shape and have abundant RNA-rich cytoplasm with refractile granules containing lysosomes. The exact function of Paneth cells is unknown, but they are thought to be capable of phagocytosing bacteria from the crypt lumen. The endocrine cells are also known as APUD cells. This term is derived from a basic characteristic of these enteroendocrine cells: uptake and decarboxylation of amine precursors. These gut endocrine cells were once thought to be of ectodermal origin but are now thought to arise from the undifferentiated crypt stem cells. A separate group of gut endocrine cells stain with potassium chromate and silver dyes. These are known as enterochromaffin cells or argentaffin cells. These synthesize and secrete 5-hydroxytryptophan (5-HTP) and 5-hydroxytryptamine (5-HT) in addition to a variety of peptide hormones such as motilin, substance P and others. The other important cellular components of the villus are lymphocytes, which are subdivided into those in the basal lamina (lamina propria lymphocytes) and those found among the epithelial cells covering the villus (intraepithelial lymphocytes).

Physiology

The primary function of the small intestine is the digestion and absorption of nutrients. The other functions of the small bowel include synthesis of lipoproteins and various hormones.

Transport

Transport of molecules and ions across the epithelium of the small intestine occurs by two routes: (1) the transcelluar route across the plasma membrane of the epithelial cells and (2) the paracellular route across tight junctions between the epithelial cells with some molecules, e.g. water, being transported by both routes. As the tight junctions are impermeable to large dietary organic molecules, e.g. amino acids and glucose, these are transported exclusively by the transcellular route through the enterocytes which have the necessary specific transporter molecules.

The absorptive epithelium of the gut is not uniform throughout its length. In particular, the permeability of the tight junctions linking cells varies considerably in the different regions of the small intestine. As the digested food travels caudally, it is exposed sequentially to regions of mucosa with different absorptive characteristics as a result of phenotypic differences of the enterocytes, i.e. the number and type of transporter molecules expressed and the permeability of the tight junctions. Even within a given segment of the small intestine, there are major differences in the types of transport, e.g. the transport in crypt cells differs from that of the villi in any given segment.

Small bowel secretion

Large quantities of water are secreted into the lumen of the small intestine during the digestive process. Almost all of this water is reabsorbed in the small intestine. Regardless of whether it is being secreted or absorbed, water flows across the mucosa in response to osmotic gradients. In the case of secretion, two distinct processes establish an osmotic gradient that pulls water into the lumen of the intestine.

1. *Increases in luminal osmotic pressure resulting from entry and digestion of chyme:* on entry into the small bowel, chyme is further digested in the small bowel with a substantial increase in the osmolarity. As the small bowel luminal osmolarity increases with digestion of foodstuffs, a net transfer of water into the lumen of the small bowel occurs. Thereafter, as the osmotically active molecules (maltose, glucose and amino acids) derived from digestion are absorbed, the osmolality of the intestinal contents decreases enabling the water to be reabsorbed.
2. *Active secretion of electrolytes by crypt cells induces water secretio*n: the luminal membrane of crypt epithelial cells contains the ion channel: cyclic adenosine monophosphate (cAMP)-dependent chloride channel, also known as the cystic fibrosis transmembrane conductance regulator (CFTR). Mutations in the gene for CFTR are the cause of cystic fibrosis. CTFR enables secretion of water as follows.
   - Cl^- enters the crypt epithelial cell by cotransport with Na^+ and K^+, but Na^+ is removed from the cell by sodium pumps, and K^+ is exported through other channels.
   - Activation of adenyl cyclase by secretagogues with generation of cAMP.
   - Raised intracellular concentration of cAMP in crypt cells activates the CFTR, resulting in secretion of chloride ions into the lumen.
   - Accumulation of Cl^- in the crypts creates an electric potential attracting Na^+ into the small bowel lumen across tight junctions – hence the secretion of NaCl.
   - Finally, the NaCl in the crypt creates an osmotic gradient across the tight junctions, drawing water into the lumen.

Abnormal activation of the cAMP-dependent chloride channel (CFTR) in crypt cells from bacterial toxins which activate the adenylate cyclase in crypt enterocytes is responsible for the abnormal massive secretion of water, with severe dehydration and not infrequent death. Cholera toxin, produced by *Vibrio cholerae,* is the best known example, but several other bacterial species can induce the same potentially lethal pathology.

Small bowel absorption

It is important to stress that the single most important process occurring in the small bowel, which underlies absorption, is the establishment and maintenance of an electrochemical gradient of sodium across the epithelial cell boundary of the small bowel lumen. To remain viable, all cells have to maintain a low intracellular concentration of sodium. In the enterocytes, low intracellular sodium is maintained by a large number of Na^+/K^+ ATPases (sodium pumps) embedded in the basolateral membrane. These pumps export three sodium ions from the cell in exchange for two potassium ions, thus establishing a gradient of both charge and sodium concentration across the basolateral membrane (Figure 29.4). In essence, it is the flow and accumulation of sodium that is ultimately responsible for absorption of water, amino acids and carbohydrates.

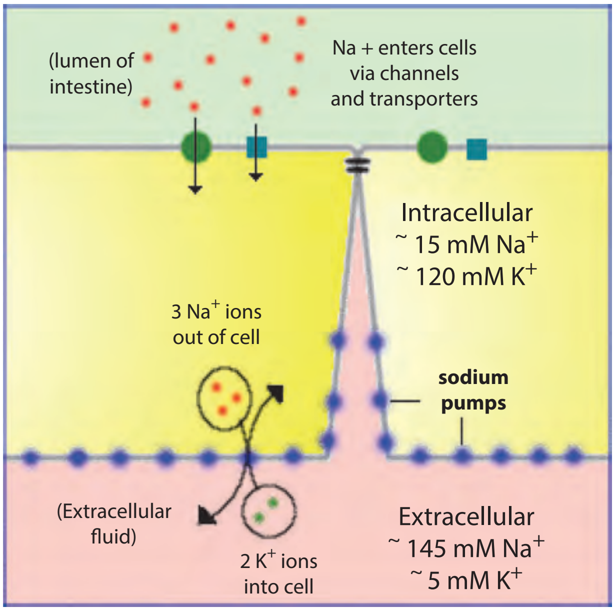

Figure 29.4 Schematic diagram illustrating the establishment of the electrochemical gradient across through the activity of sodium pumps.

Absorption of monosaccharides

Monosaccharides are derived by enzymatic digestion of more complex carbohydrates (polysaccharides). Particularly important dietary carbohydrates in man include starch and disaccharides, especially lactose and sucrose. All these molecules cannot be absorbed without prior luminal enzymatic digestion into monosaccharides by enzymes present in the brush border of the luminal plasma membrane of absorptive enterocytes and known collectively as *brush border hydrolyases*. These include maltase, lactase and sucrase. Whereas dietary lactose and sucrose are directly digested by their respective brush border enzymes, starch requires preliminary digestion to maltose by salivary and pancreatic amylases. At the brush border, maltase splits maltose into two molecules of glucose, lactase splits lactose into galactose and glucose and sucrase splits sucrose into glucose and fructose. The resultant glucose and galactose enter the enterocyte by cotransport with sodium using the same transporter, whereas fructose uses a separate transporter (GLUTS) for its entry into the enterocyte.

Transport of glucose and other monosaccharides across the intestinal epithelium

The transporter that carries glucose and galactose into the enterocyte is the sodium-dependent hexose transporter, known as SGLUT-1, which transports both glucose and sodium ions into the cell through a series of conformational changes as follows.

1. The transporter facing the lumen initially binds sodium.
2. In turn, the bound sodium induces a conformational change which opens the glucose-binding pocket of the transporter.
3. As glucose binds to the transporter, this reorientates such that the pockets carrying sodium and glucose are moved intracellularly.
4. Sodium then dissociates into the cytoplasm, thereby destabilizing the glucose binding when glucose dissociates from the transporter into the cytoplasm.
5. The unloaded transporter reorientates back to its original luminal-facing position.

Once inside the enterocyte, glucose and sodium are transferred into the bloodstream. Sodium is rapidly exported in exchange for potassium by the sodium pumps, thereby maintaining the electrochemical gradient across the epithelium. Glucose, galactose and fructose are transported out of the enterocyte into the capillary bloodstream of the villus by means of another hexose transporter (called GLUT-2) also located in the basolateral membrane.

Absorption of amino acids and peptides

Dietary proteins have to be digested prior to absorption. The enzymes involved are gastric pepsin and a group of pancreatic proteases, also secreted as zymogens and requiring activation to trypsin, chymotrypsin and carboxypeptidases. By these enzymes, dietary proteins are hydrolysed within the lumen of the small intestine predominantly into amino acids, medium and small peptides (oligopeptides). The brush border peptidases are responsible for the further hydrolysis of luminal peptides into free amino acids and very small peptides. The di- and tripeptides, which have a high affinity for the brush border peptidases, are hydrolysed to individual amino acids before absorption. Those with a low affinity for the brush border enzymes are absorbed intact by the enterocytes.

The luminal plasma membrane of the enterocytes also has sodium-dependent amino acid transporters – one each for acidic, basic and neutral amino acids. These transporters bind amino acids only after binding sodium. The fully loaded transporters then undergo a conformational change that releases the sodium and the amino acid into the cytoplasm, followed by its reorientation back to the original form. Thus, as with monosaccharides, the absorption of amino acids is also dependent on the electrochemical gradient of sodium across the epithelium. The basolateral membrane of the enterocyte contains additional transporters which export amino acids from the enterocytes into the bloodstream but these are not dependent on sodium gradients.

Both di- and tripeptides are also absorbed in abundance by the mucosa of the small intestine by cotransport with H^+ ions via a transporter called PepT1. Once inside the enterocyte, the majority of the absorbed di- and tripeptides are digested into amino acids by cytoplasmic peptidases and exported from the cell into blood, with only a very small fraction entering the bloodstream intact. For a few days after birth, neonates have the ability to absorb intact proteins. This ability, which is rapidly lost, is of immense importance because it enables the newborn baby to acquire passive immunity by absorbing immunoglobulins present in colostral milk.

Absorption of lipids

Although the bulk of dietary lipid is made up of triglycerides, food also contains phospholipids, sterols especially cholesterol and many other lipids, including fat-soluble vitamins. Triglyceride absorption entails two processes: (1) emulsification followed by (2) enzymatic digestion to monoglycerides and fatty acids.

Bile acids are responsible for emulsification by virtue of their amphipathic nature, i.e. they have both hydrophilic and hydrophobic domains. On exposure to large aggregates of triglycerides, the hydrophobic portions of bile acids intercalate and surround the lipid aggregates in a specific way that results in the hydrophilic domains being exposed at the surface. Aside from the breaking up of large lipid aggregates into progressively smaller ones, the external hydrophilic domains ensure aqueous dispersion in the fluid of the small bowel content.

Pancreatic lipase and colipase are responsible for the hydrolysis of the emulsified triglycerides by splitting the fatty acids at positions 1 and 3 of the triglyceride chain with the production of two fatty acids and one 2-monoglyceride.

The monoglycerides and fatty acids produced by the action of lipase retain their association with bile acids and complex with other lipids to form micelles, which are essentially small aggregates (4–8 nm in diameter) of mixed lipids and bile acids suspended within the intestinal fluid. At the surface of the enterocytes the monoglycerides and free fatty acids separate from the micelles before entering the enterocyte, leaving the bile acids within the intestinal lumen. At the brush border lipids, including monoglycerides and fatty acids, are taken up into the epithelial cells.

Lipid transport into the blood

Both fatty acids and 2-monoglycerides enter the enterocytes by simple diffusion, but considerable amounts of the fatty acids are transported into the enterocytes via a specific fatty acid transporter protein. Once inside the enterocyte, fatty acids and monoglycerides are bound to fatty acid-binding proteins (FABPs) and transported to the smooth endoplasmic reticulum where they are re-esterified. Within the Golgi apparatus of the endoplasmic reticulum, the triglycerides are converted to chylomicrons consisting of cholesterol and triglyceride surrounded by phospholipids, free cholesterol and apoproteins. These chylomicrons together with lipoproteins are transferred via the lacteals and lymph channels and ultimately through the thoracic and left lymphatic trunks into the venous blood.

The absorption of medium chain triglycerides (MCTs) on the other hand is different. A significant percentage of MCTs is absorbed intact into the portal blood. The rest is broken down by pancreatic lipase to medium chain fatty acids which are readily absorbed by the intestinal cells after micellar aggregation with bile acids. These are then transferred as free fatty acids into the portal venous blood without chylomicron formation.

Cholesterol homeostasis results from a balance of cholesterol synthesis, absorption of dietary cholesterol and excretion in bile. A specific transport protein (NPC1L1) is responsible for transport of cholesterol from the intestinal lumen into the enterocyte, where the bulk is esterified and incorporated into chylomicrons.

Under normal circumstances, the digestion and absorption of fluid, electrolytes, iron, folates, carbohydrates, fat and proteins is completed in the jejunum. However, the effective absorption of bile salts and vitamin B_{12} can only occur in the terminal ileum, as these substances require specific transport sites which are located in this region. In the absence of ileum the critical length of jejunum required for the absorption of water-soluble substances is somewhere between 30 and 120 cm. However, the absence of the ileum will produce malabsorption of fat from a diminished bile salt pool and of vitamin B_{12}. The ileum on the other hand is able to perform all the absorptive functions of the jejunum if the proximal small bowel is excised.

Other functions of the small intestine

Another function of the small intestine is the synthesis of high-density, low-density and very low-density lipoproteins (HDL, LDL, VLDL). These are closely related to the chylomicrons and contain the same apoproteins. The intestinal lipoproteins reach the plasma via the thoracic duct. Although there are other tissues which synthesize these lipoproteins, e.g. the liver, the gastrointestinal tract is a major site of production and therefore plays an important part in the metabolism of plasma lipoproteins. The synthesis of these lipoproteins by the small intestine is impaired in kwashiorkor.

The third function of the small intestine is the synthesis of peptide and amine intestinal hormones. These are located within the enteroendocrine cells and in the neurones of the myenteric plexus. These modulate intestinal activity in three ways: (1) as classic endocrine hormones, (2) neurotransmitters and (3) as hormones with a paracrine action. These hormones influence intestinal secretion and transport, growth and differentiation, the splanchnic haemodynamic state and the release of insulin (Table 29.1).

Table 29.1 Hormones originating in the small bowel and their functions

Hormone	Functions
Acetylcholine	Neurotransmitter
Enkephalins	Neurotransmitter
Enteroglucagon	Growth and differentiation
Gastric inhibitory peptide	Glucose-dependent insulin release
Glucagon	Increased splanchnic blood flow
Motilin	Secretion and transport
Neurotensin	Increased splanchnic blood flow, secretion and transport
Noradrenaline	Neurotransmitter
Secretin	Secretion and transport
Serotonin	Neurotransmitter
Somatostatin	Neurotransmitter, secretion and transport
Substance P	Neurotransmitter
Vasopressin	Decreased splanchnic blood flow
Vasoactive intestinal peptide	Increased splanchnic blood flow

The complex hormonal interactions within the small intestine are closely linked with the activity of the enteric nervous system, which is considered to act as an independent integrative system regulating reflex activity within the gut. Within the myenteric plexus, neurones containing opioid peptides (enkephalins), substance P, vasoactive intestinal peptide (VIP), serotonin and somatostatin have all been identified in addition to the better known adrenergic [noradrenaline (norepinephrine)] and cholinergic (acetylcholine) neurotransmitters.

Small intestinal motility

The co-ordinated contractions of the small intestine after a meal (fed pattern) are designed to facilitate digestion and absorption by:

- ensuring adequate mixing of the ingested foodstuffs with the pancreatic digestive enzymes and with bile salts entering the small bowel through the sphincter of Oddi as a result of co-ordinated contractions of the gallbladder after a meal induced by cholecystokinin
- constant dispersal of nutrient molecules in the bowel lumen derived by digestion, thus bringing them in close contact with the enterocytes where enzymatic digestion is completed and absorption occurs
- advancing the chyme down the small bowel, thereby making space for the next load delivered from the stomach.

Motility in the small intestine is controlled predominantly by excitatory and inhibitory signals from the enteric nervous system modulated by input from the central nervous system (CNS) and a number of gastrointestinal hormones. Studies of gastrointestinal motility are difficult to undertake and to interpret. Most have been performed with multilumen fluid-perfused catheters attached to external transducers linked to chart recorders. However, solid-state systems based on several miniature strain gauge transducers mounted at intervals on a fine catheter are now commonly used. The analogue signals (corresponding to the intestinal contractions) from these transducers are stored in a solid-state external portable logger. The data are then offloaded onto a computer for analysis. Software systems are now available which are capable of sophisticated analysis of small bowel activity.

Using these new systems it has been possible to characterize small bowel motility both in normal and in pathological states. In the normal situation both fasting and fed patterns of intestinal activity are now recognized and the types of intestinal contractions fall into two categories, *mixing* and *propagating*. The mixing contractions include the *stationary ring contractions*, which occlude the lumen at one point and push the intestinal contents in both directions, and the *stationary cluster contractions*, which may occur at one or several sites simultaneously. The propagating contractions include *single propagated contractions*, *propagating power contractions*, *migrating cluster contractions* and *the phase III of the migratory motor complex (MMC)*. The propagating power contractions are also known as the giant migratory contractions. They correspond to the peristaltic rushes described by earlier workers and are effective at sweeping intestinal contents in a distal direction at a rapid rate. They are increased in patients undergoing radiotherapy and are now thought to be the cause of the nausea, vomiting, abdominal pain and diarrhoea which are often experienced by these patients.

In the interdigestive period between meals, the small bowel is empty due to the MMC consisting of contractions which originate in the stomach and sweep down the entire length of the small intestine, sometimes causing audible borborygmi.

Motility disorders may be functional (no definable organic cause) or secondary to myopathy (hollow visceral type), autonomic neuropathy, abnormalities of the enteric nervous system, endocrine disorders, tumours, drug-induced and multiple endocrine neoplasia. The motility disorders of the small and large intestine that are of surgical importance include adynamic (paralytic) ileus, irritable bowel syndrome, slow transit constipation and Hirschsprung disease.

Microbiology

At birth the alimentary tract is sterile but becomes colonized by bacteria via the oral route, so that within 3–4 weeks of birth the enteric microflora found in the adult are already established. The stomach, duodenum and proximal jejunum in the normal adult subject contain transient Gram-positive aerobes such as lactobacilli and enterococci in concentrations of less than 10^4 colony-forming units (CFU) per mL of contents. In the terminal ileum, however, the bacterial counts are higher (10^5–10^8 CFU) and the flora resemble that of the large bowel. The organisms encountered include coliforms and strict anaerobes (e.g. bacteroides). Substantially higher bacterial counts (10^5–10^{11} CFU) are found in the colon, with bacteroides, anaerobic lactobacilli and clostridia predominating. It is thought that the small bowel microflora play an important protective role against bacterial overgrowth and infection by preventing colonization of the surface epithelium by pathogenic bacteria. This is brought about by production of bacteriocins (antibiotics) and lowering of the oxidation–reduction potential by anaerobic metabolism, which results in the production of substances that are toxic to bacteria.

Intraluminal bacteria produce endotoxin which is not absorbed into the bloodstream in the presence of bile salts. However, absorption of endotoxin into the blood occurs whenever bile salts are prevented from reaching the small intestine as in obstructive jaundice. This endotoxinaemia may be responsible for the development of renal failure after surgical intervention in jaundiced patients. The small bowel microflora play an important role in intraluminal metabolism of various substances, particularly metabolized protein and other nitrogenous compounds, the results of which are absorbed and used for synthesis of amino acids. For example, the excess ammonia produced by bacterial metabolism after an episode of gastrointestinal haemorrhage may precipitate encephalopathy in patients with chronic liver disease and portal hypertension. Under normal conditions a symbiotic relationship exists between the gut and intestinal organisms, and indeed the villous architecture and rate of regeneration of the intestinal mucosa depend on the presence of a normal resident microflora. However, in conditions of stasis and diminished or absent gastric secretory activity, bacterial overgrowth may occur leading to maldigestion and malabsorption.

Gut mucosal integrity and bacterial translocation

The normal intestinal mucosa in the presence of a competent immune system is able to resist invasion by pathogenic bacteria. This antimicrobial barrier can break down under certain pathological states with translocation of the pathogens to the blood and lymph, with subsequent systemic invasion of tissues and organs. Such bacterial translocation underlies one of the hypotheses held responsible for systemic inflammatory response syndrome, i.e. endotoxin-induced activation of the cytokine cascade, which in turn leads to multiorgan failure (MOF) and death. This hypothesis has, however, been challenged recently, because treatment with antibodies to the polysaccharide fraction of endotoxin has been shown to be ineffective in clinical trials, and other mechanisms, e.g. endothelial damage by activated neutrophils, may be responsible for MOF. The conditions that promote bacterial translocation are:

- bacterial overgrowth
- immunodeficiency
  - physical disruption of mucosa including ischaemia
- trauma
  - burns
- sepsis
- endotoxinaemia and protein malnutrition.

In septic patients enteral feeding with complete diets may nonetheless protect the integrity of the gut barrier and improve the immune function and is thus superior to parenteral feeding. The components of enteral feeds which have been shown to enhance the ability of the intestinal mucosa to resist bacterial translocation are arginine, glutamine and lipids (especially fish oil). Arginine, a dibasic amino acid, can stimulate the secretion of insulin, prolactin and growth hormone and also has immunomodulatory effects. Thus in immunocompromised patients, arginine supplements have been shown to enhance lymphocyte function in the postoperative period. There is also good evidence that dietary lipids may have a similar effect. This may act directly or indirectly via alterations in eicosanoid metabolism. The eicosanoids include prostaglandins and leukotrienes that modulate the inflammatory response and immune function. Glutamine is the most abundant amino acid in the free amino acid pool and is essential for all rapidly dividing cells including enterocytes. It thus plays an important role in maintaining the integrity of the intestinal mucosa. Although the glutamine pool is large, it is labile and becomes rapidly depleted in injured and septic patients. Thus in the critically ill, glutamine may be regarded as an essential amino acid. There is good evidence that the translocation of bacteria encountered in sepsis, trauma and burns may be reversed by glutamine-enriched intravenous or enteral nutrition. This positive effect is accompanied by a normalization of the secretory IgA levels and a decrease in the bacterial adherence to enterocytes.

Small bowel investigations

Specific investigation of the small intestine is indicated where small bowel obstruction, bleeding or malabsorption are suspected. The term malabsorption can be used to describe the failure to absorb specific substances, e.g. carbohydrates, fats, proteins, minerals, etc., but when used unqualified it generally refers to fat malabsorption. This is frequently encountered in surgical practice as it may follow excisional and bypass procedures in the gastrointestinal tract which effectively shorten the small bowel and may contribute to bacterial overgrowth. Clearly, serum biochemistry, e.g. albumin, transferrin, electrolytes, including calcium, iron, haemoglobin level and blood film, are all necessary when malabsorption is suspected. There are however special investigations which may assist in establishing the diagnosis.

Radiology

The radiological investigations that are of value in resolving pathologies which may affect the small bowel include plain radiography, barium studies, fistulography, ultrasound and CT scanning, mesenteric angiograph and isotope studies.

Plain radiography

Plain abdominal radiographs provide useful information in the diagnosis of the acute abdomen. As far as the small bowel is concerned, obstruction is diagnosed by visualizing dilated gas-filled loops of small bowel. These can be distinguished from large bowel by the more central distribution and the ladder-like valvulae conniventes. Traditionally, an erect abdominal film is obtained at the same time but this does not provide any extra information, although it is only on the erect film that the typical fluid levels will be seen. Occasionally, however, obstructed small bowel may be so full of fluid that it will not be seen clearly on the supine film and the fluid levels will only be seen on the erect film which will give the diagnosis. Thickening of the small bowel can be inferred when there is a significant gap between the gaseous outline of the lumen of adjacent loops of small bowel. Plain radiography is also very useful for identifying free air in the peritoneum, but it must be remembered that an erect chest radiograph is more useful in this respect, as in the erect abdominal film the diaphragm may not be included.

Barium studies

The mainstay of the investigation of the small bowel is the barium small bowel follow-through which is easy to perform as part of a barium meal study. However, a small bowel enema in which contrast medium is instilled via a Bilbao–Dotter tube directly into the upper jejunum carries a higher diagnostic yield, especially for small bowel tumours and in patients with suspected malabsorption. In particular, ulcers, sinuses and fistulas are better visualized by a small bowel enema (enteroclysis). The radiological criteria of malabsorption are flocculation and segmentation of the barium, thickening of the mucosal folds and dilatation of intestinal loops. It must be stressed however that these changes are non-specific and the diagnosis must be confirmed by other more specific tests.

There have been few comparative studies between barium meal and follow-through and small bowel enema (enteroclysis), but available evidence indicates that the latter is superior except in Crohn's disease. The false-negative rate for the detection of primary small bowel neoplasms is much higher (80%) for follow-through examinations than small bowel enema (10%). Enteroclysis is better than follow-through and even radionuclide studies for the detection of Meckel's diverticulum. Small bowel enema is useful in the diagnosis of partial/intermittent obstruction and is superior to both follow-through and CT in these cases. In contrast, CT is accurate in showing site and cause in patients with established high-grade obstruction.

In the patient with obstruction due to adhesions where there are some doubts as to whether or not the obstruction will settle with conservative treatment, it is useful to give the patient a drink or nasogastric bolus of water-soluble contrast such as 40 mL of Urografin in 40 mL of distilled water. If the contrast has not reached the ascending colon within 24 hours, it is highly likely that the patient will require surgical intervention.

Injection of contrast into the fistula may also be of value (fistulography). This is particularly useful in Crohn's disease. Where enterocutaneous fistulas have formed, fistulography will allow the diagnosis of associated abscess cavities and strictures and will aid the planning of appropriate surgical intervention.

Ultrasound and CT scanning

Ultrasound scanning may be used in patients with intestinal obstruction and is capable of differentiating fluid-filled dilated intestinal loops from other cystic structures within the abdomen, but its role in the investigation of small bowel disease is limited. CT scanning of the small intestine entails the use of a special barium sulphate suspension (E-Z-CAT) to opacify the lumen of the intestine. It is useful in detecting thickening of the bowel wall and in demonstrating the presence of enterocolic and enterovesical fistulas. However, indications for its use in small bowel disorders are limited since the information can often be obtained by standard contrast radiology.

Small bowel enteroscopy

Endoscopy of the small bowel can be performed either by using a long balloon-tipped small bowel enteroscope or by using a 'push' enteroscope. With the former, the balloon is inflated after the endoscope has entered the duodenum and this enables gut peristalsis to carry the tip of the enteroscope to the caecum (Figure 29.5). This is established by radiological screening, and inspection of the bowel is performed as the

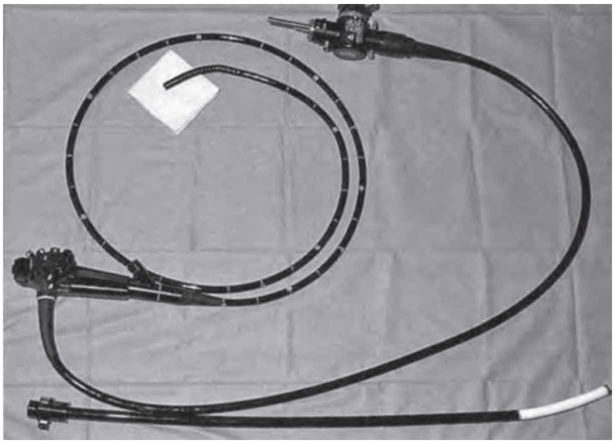

Figure 29.5 Small bowel enteroscope. Note the stiffening overtube at the bottom of the picture.

instrument is slowly withdrawn. This is useful in difficult diagnostic areas such as recurrent obscure bleeding and has shown that many patients with bleeding from non-steroidal anti-inflammatory drugs have duodenal ulcers. The limitations of this type of equipment include the time required to carry out the procedure (in the region of 6 hours) and the inability to biopsy through the enteroscope. The push enteroscope on the other hand can be used to take biopsies, but only the first 60 cm or so of the small bowel beyond the duodenojejunal flexure can be visualized.

A more recent development is double-balloon endoscopy (DBe) and is described together with capsule endoscopy (CE).

Mesenteric angiography

Selective mesenteric angiography can be used to detect angiodysplastic lesions and vascular tumours in the small bowel, which can lead to occult or frank bleeding from the gastrointestinal tract. It is also possible to detect an active bleeding site in the small intestine by this means if blood is being lost at more than 0.5 mL/min. If a bleeding point is identified during mesenteric angiography, it is helpful if the radiologist can place a superselective catheter into the appropriate branch of the SMA to lie as close as possible to the lesion. The catheter is then left *in situ* when the patient goes to the operating theatre. The surgeon can then inject contrast (methylene blue) along the catheter and the segment of small bowel in which the bleeding lesion is present can easily be identified (Figure 29.6). However, mesenteric angiography has been largely superseded by CE and DBe, except in life-threatening bleeding where radiological control by selective embolization of the lesion may be life saving or provide time for resuscitation and urgent surgical intervention.

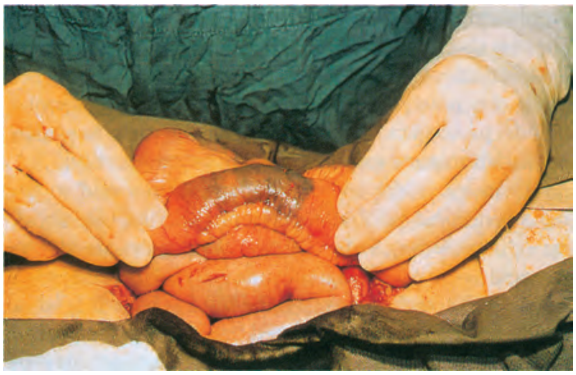

Figure 29.6 Segment of small bowel highlighted by intraoperative injection of methylene blue via superselective mesenteric angiogram catheter.

Capsule endoscopy

CE, introduced in 2000 by Given Imaging is a natural consequence of advances in complementary metal oxide semiconductor (CMOS) sensing technology. CE entails the ingestion of a miniature, pill-sized camera that moves through and visualizes the mucosa of the digestive tract. CE enables inspection of the gastrointestinal tract without discomfort or need for sedation, and thus obviates the risks associated with traditional endoscopy. The first capsule, PillCam SB (Given Imaging, Yoqneam, Israel) was specifically designed for the diagnosis of disorders of the small intestine. The capsule houses a CMOS camera that acquires two images per second during its passive progression through the lumen of the gastrointestinal tract and has a battery life of approximately 8 hours. The visual data obtained by the CMOS camera are sent to a data logger worn by the patient. Following the completion of the CE, the visual data are loaded on to a dedicated PC for viewing (Figure 29.7).

Since then the same company has produced the PillCam ESO for investigation of disorders of the oesophagus and the PillCam Colon for inspection of the colon (see relevant chapters). Within a reasonably short period of time CE has become established in routine clinical practice especially for the investigation of patients with small bowel disorders.

Several large retrospective and prospective clinical studies have confirmed the superior safety and efficacy of CE compared with all other investigations for the diagnosis of obscure gastrointestinal bleeding. It has thus become the investigation of choice in these patients, largely superseding all other investigations. The role of CE in the evaluation of Crohn's disease remains unclear. In contrast, CE has become the key diagnostic test for patients with suspected tumours of the small bowel. There is also good published evidence that CE is useful for the diagnosis of villous atrophy (coeliac disease).

CE has a number of limitations. These include low diagnostic specificity, risk of capsule retention, inability to detect the exact site of the disease, limited battery power, absence of active propulsion and inability to control the orientation of the CMOS camera. The projection is however that, as the technology advances to overcome all the present limitations, CE will ultimately replace conventional endoscopy.

Small bowel CE with PillCam SB

Meticulous bowel preparation is essential for CE to avoid smudging of the camera lens, since the capsule has no irrigation facilities. The small bowel preparation includes ingestion of

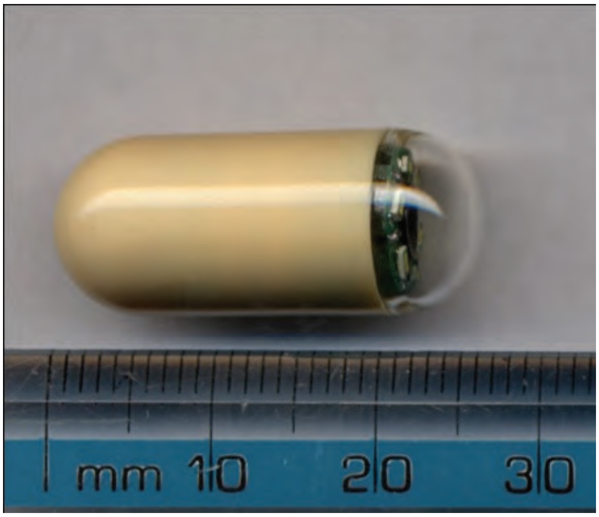

Figure 29.7 PillCam SB: actual capsule which is swallowed by the patient.

1.0 L of clear liquid or polyethylene glycol 12 hours before the examination.

Although the use of prokinetic agents to facilitate propulsion of the capsule and overcome any stoppages at sphincter sites (pylorus), the results of the reported studies on the effect of prokinetics on CE have been contradictory. The largest published series of CE for obscure gastrointestinal bleeding, which included 260 patients, reported a diagnostic yield of CE of 60% and 46% for overt and occult bleeding respectively.

Lesions identified by CE may be treated by DBe (Figure 29.8a) developed by Fujinon (Saitama, Japan). CE and DBe are thus complementary techniques. The complementary role of CE and DBe in the detection of the cause and in the management of obscure gastrointestinal bleeding has been evaluated in a prospective study. This showed a higher sensitivity (90.6% vs 65.6%) and diagnostic yield (71.9% vs 65.9%) for CE than for DBe. However, DBe has the advantage of obtaining biopsy samples and, in suitable cases, successful treatment of lesions. Some practical difficulties have been reported with the use of DBe, including attachment of the balloon to the tip of the endoscope before each examination, and inflation/deflation of the two balloons with every insertion. Additionally, care must be taken during cleaning of the endoscope to avoid blockage of the small air hole at the tip of the device. The single-balloon enteroscopy technique, developed in 2008 by Olympus (Tokyo, Japan), is more manageable than DBe, as it requires the endoscopist to inflate only one balloon (Figure 29.8b). Furthermore, the single-balloon enteroscopy device is easier to clean than the DBe.

Isotope studies

External isotope scintigraphy following the intravenous administration of radiolabelled compounds or isotope-labelled autologous cells can be useful in the investigation of patients with occult gastrointestinal bleeding. It may also be useful in detecting inflamed intestine and in estimating the intestinal transit time.

Intestinal bleeding

Haemorrhage of small intestinal origin may be due to Meckel's diverticulum, polyps, jejunal ulcers, tumours or vascular malformations. These may not be detectable using endoscopy, small barium studies or angiography. Under these circumstances, radionuclide methods may help to solve the problem, although again as with mesenteric angiography they have been largely superseded by CE and DBe when these are available.

Basically there are three isotope methods. The first involves the injection of technetium pertechnetate. This is the method of choice for the detection of bleeding Meckel's diverticulum and carries an accuracy rate of 90%. The technetium is concentrated by ectopic gastric mucosa in the diverticulum which can be identified as a hot spot (Figure 29.9). For the detection of rapidly bleeding sites in the emergency situation ^{99m}Tc sulphur colloid can be used following intravenous bolus injection. It is cleared from the circulation by the macrophage system within 15 minutes, at which point the blood radioactivity declines, but the extravascular radioactivity at the bleeding site increases thereby allowing its detection as a hot spot by external scintigraphy. In practice, this method is rarely used as mesenteric angiography gives a much more accurate anatomical localization and enables therapeutic embolization of the lesion.

In the patient with intermittent gastrointestinal bleeding, however, technetium-labelled autologous red cells may be useful. These are cleared much more slowly from the vascular compartment following their intravenous injection and the method allows repeated examinations over a 24 hour period (Figure 29.10). Its main disadvantage is that it takes time to label the patient's red blood cells and it is therefore unsuitable for the actively bleeding patient.

Estimation of small bowel transit time

In the past, small bowel intestinal transit studies have been performed using radio-opaque solid, non-absorbable chemical markers. These however are generally regarded as being unphysiological and unsuitable for routine clinical practice. Estimation of the small bowel transit is best performed either by external scintigraphy after administration of isotope-labelled meals or by breath tests (see below). Both liquid and solid meals labelled with technetium sulphocolloid or diethylamine penta-acetic acid can be used to estimate simultaneously gastroemptying and small bowel transit time. The detection of caecal radioactivity is used as the end point for the estimation of the small bowel transit time.

Detection of small bowel inflammatory disease

Indium-labelled autologous leucocytes when injected intravenously settle in areas of inflammation or abscess formation. This can be used to detect the extent of active

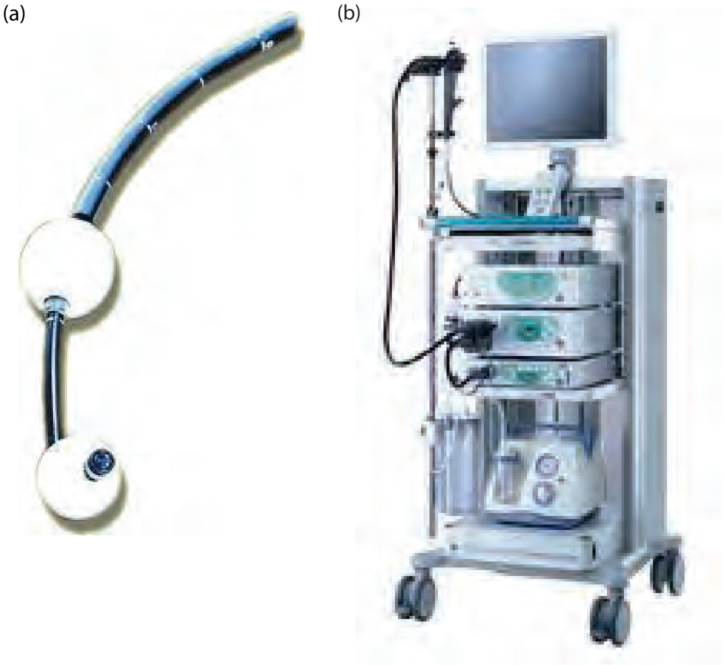

Figure 29.8 (a) Fujinon double-balloon endoscope: enables isolation of a segment between the two balloons which enables treatment of certain small bowel lesions. (b) Olympus single endoscope: also enables treatment of certain small bowel lesions.

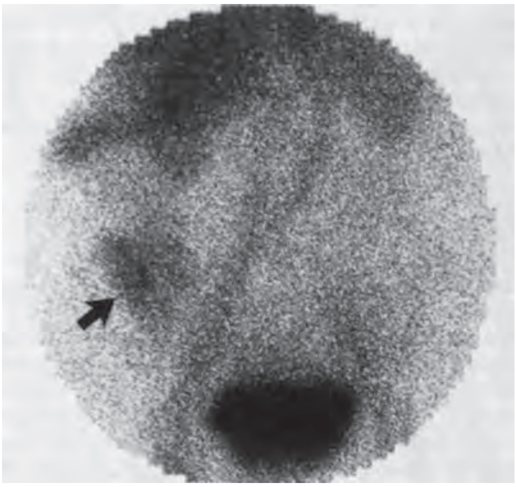

Figure 29.9 Ectopic gastric mucosa in a Meckel's diverticulum outlined by external scintiscanning after the intravenous administration of ^{99m}Tc.

inflammatory bowel disease and assess its severity. However, there can be great difficulty with interpretation because of the increased background radioactivity produced by the uptake of the radiolabelled leucocytes by the bone marrow, liver and spleen. Another approach is to use labelled sucralfate. Sucralfate is an aluminium salt of polysulphated sucrose which is used in the treatment of peptic ulceration. It binds selectively to areas of mucosal ulceration within the gastrointestinal tract and labelled sucralfate has proved to be a useful technique in the detection of inflammatory bowel disease in both the large and the small intestine. In view of its lower radiation dosage than barium studies, it can be used as a screening test and in the serial assessment of disease activity. The labelled suspension of sucralfate is administered by mouth, and serial isotope scans of the abdomen are carried out at 2, 6, 20 and 24 hours.

Investigations for malabsorption

Malabsorption implies the inability to absorb sufficient nutrient owing to disease of the gastrointestinal tract. It is most commonly due to dysfunction of the small bowel or the pancreas. The most common clinical feature is steatorrhoea from malabsorption of fat. Symptoms attributable to failure to absorb carbohydrate and protein are not so common and may consist of abdominal discomfort and bloating. Digested carbohydrate is fermented to lactic acid in the large bowel, which can lead to diarrhoea. The investigation of a patient with suspected malabsorption should start with the estimation of faecal fat. Once steatorrhoea is confirmed further tests are required to establish the nature of the underlying pathology. These tests help to differentiate whether the malabsorption is of small bowel origin (e.g. small intestinal disease or bacterial overgrowth) or the result of pancreatic exocrine insufficiency.

Estimation of faecal fat

The quantitative estimation of faecal fat remains the most sensitive and reliable test of disorders of digestion and absorption. The faecal fat output per day is estimated on a 3–5 day collection on a standard diet containing 80–100 g of fat. The normal is less than 6.0 g per day (80 mmol of triglyceride). Other tests such as the ^{14}C-triolein breath test and oxalate-loading test are less reliable but are used in some centres as screening tests for steatorrhoea.

Duodenal mucosal biopsy

Biopsy taken at upper-gastrointestinal endoscopy of the distal duodenum can be used to look for abnormalities of villous architecture, e.g. subtotal villous atrophy in coeliac disease (Figure 29.11). In addition, abnormal mucosal pathogens may be detected as in Whipple disease in addition to parasites, e.g. *Giardia lamblia* (Figure 29.12). Endoscopic duodenal biopsy has largely replaced the use of the suction Crosby capsule.

The Schilling test

The absorption of vitamin B_{12} by the terminal ileum requires the presence of intrinsic factor and to a lesser extent the R protein in the gastric juice. In the Schilling test radiolabelled vitamin B_{12} (1.0 μg) is administered orally immediately after a large parenteral injection of the unlabelled vitamin (1000 μg) to ensure saturation of the body stores. Under these conditions, normal subjects will excrete 10% or more of the radiolabelled vitamin in their urine. If abnormally low excretion is found in a patient, the test is repeated but the labelled vitamin B_{12} is given together with intrinsic factor. In the presence of ileal disease, the abnormally low excretion of the labelled vitamin in the urine is not altered by the addition of the intrinsic factor. However, in patients with pernicious anaemia or after total gastrectomy the administration of intrinsic factor restores the urinary excretion of the labelled vitamin to normal. Both stages of the test are invalidated by dehydration and renal disease. Bacterial overgrowth may cause malabsorption of the vitamin and an abnormal Schilling test, but this will revert to normal after a course of antibiotic therapy.

SeHCAT bile absorption test

This test estimates the ability of the terminal ileum to absorb bile acids. The synthetic selenium bile acid known as SeHCAT is used. A dose of this ^{75}Se-labelled compound is administered orally or intravenously and a gamma-counter is used to estimate the bile acid absorption. There is a very good correlation between the results of the SeHCAT test and faecal excretion of bile acids.

^{14}C-glycocholate and the ^{14}C-D-xylose breath tests

The ^{14}C-glycocholate breath test is used to detect bacterial overgrowth in the small intestine. The glycine moiety of the conjugated bile salt is labelled with ^{14}C and ingested to mix with the endogenous bile salts in the intestine. Normally the bile salts are largely reabsorbed intact in the terminal ileum to enter the enterohepatic circulation and only a small amount reaches the colon, where it is deconjugated by the colonic bacteria and the glycine metabolized to yield $^{14}CO_2$. This is absorbed and eliminated in the expired air. However, in the presence of bacterial overgrowth most of the ingested labelled salt is deconjugated by the small bowel bacteria and excess $^{14}CO_2$ is produced and eliminated in the expired air (Figure 29.13). False-positive results are obtained with this test in the presence of ileal disease. The ^{14}C-D-xylose test is more reliable in this respect. D-Xylose is a pentose which is normally absorbed intact by the same transport mechanism as the hexoses.

Breath tests for carbohydrate malabsorption

The analysis of breath $^{14}CO_2$ following the ingestion of ^{14}C-lactose is a convenient test for lactose intolerance resulting from a deficiency of the brush border enzyme lactase. This test is easy to perform, is as accurate as the lactose tolerance test and agrees reasonably well with mucosal disaccharidase activity. Hydrogen is produced when carbohydrate is fermented by some bacteria. When there is lactose malabsorption the sugar reaches the colon, where it is fermented with the production of hydrogen. A proportion of this gas is absorbed and excreted in the expired air. Using mass spectrometry it is possible to measure very low concentrations of hydrogen in a sample of end-expiratory air which has a similar composition to that of alveolar air. There is evidence that the breath hydrogen concentration is more accurate than $^{14}CO_2$ excretion for the diagnosis of lactase deficiency. Both tests give false-positive results in patients with bacterial overgrowth (Figure 29.14).

Hydrogen breath tests for measurements of small bowel transit time and bacterial overgrowth

The hydrogen breath test is a useful and reliable method for determining small bowel transit time. Repeated measurements of the hydrogen in the end-expiratory air are taken every few minutes after the ingestion of a meal. The latter may be liquid in nature (drink of the non-absorbable sugar lactulose) or solid, usually mashed potatoes and baked beans, which contain non-absorbable oligosaccharides. When the meal

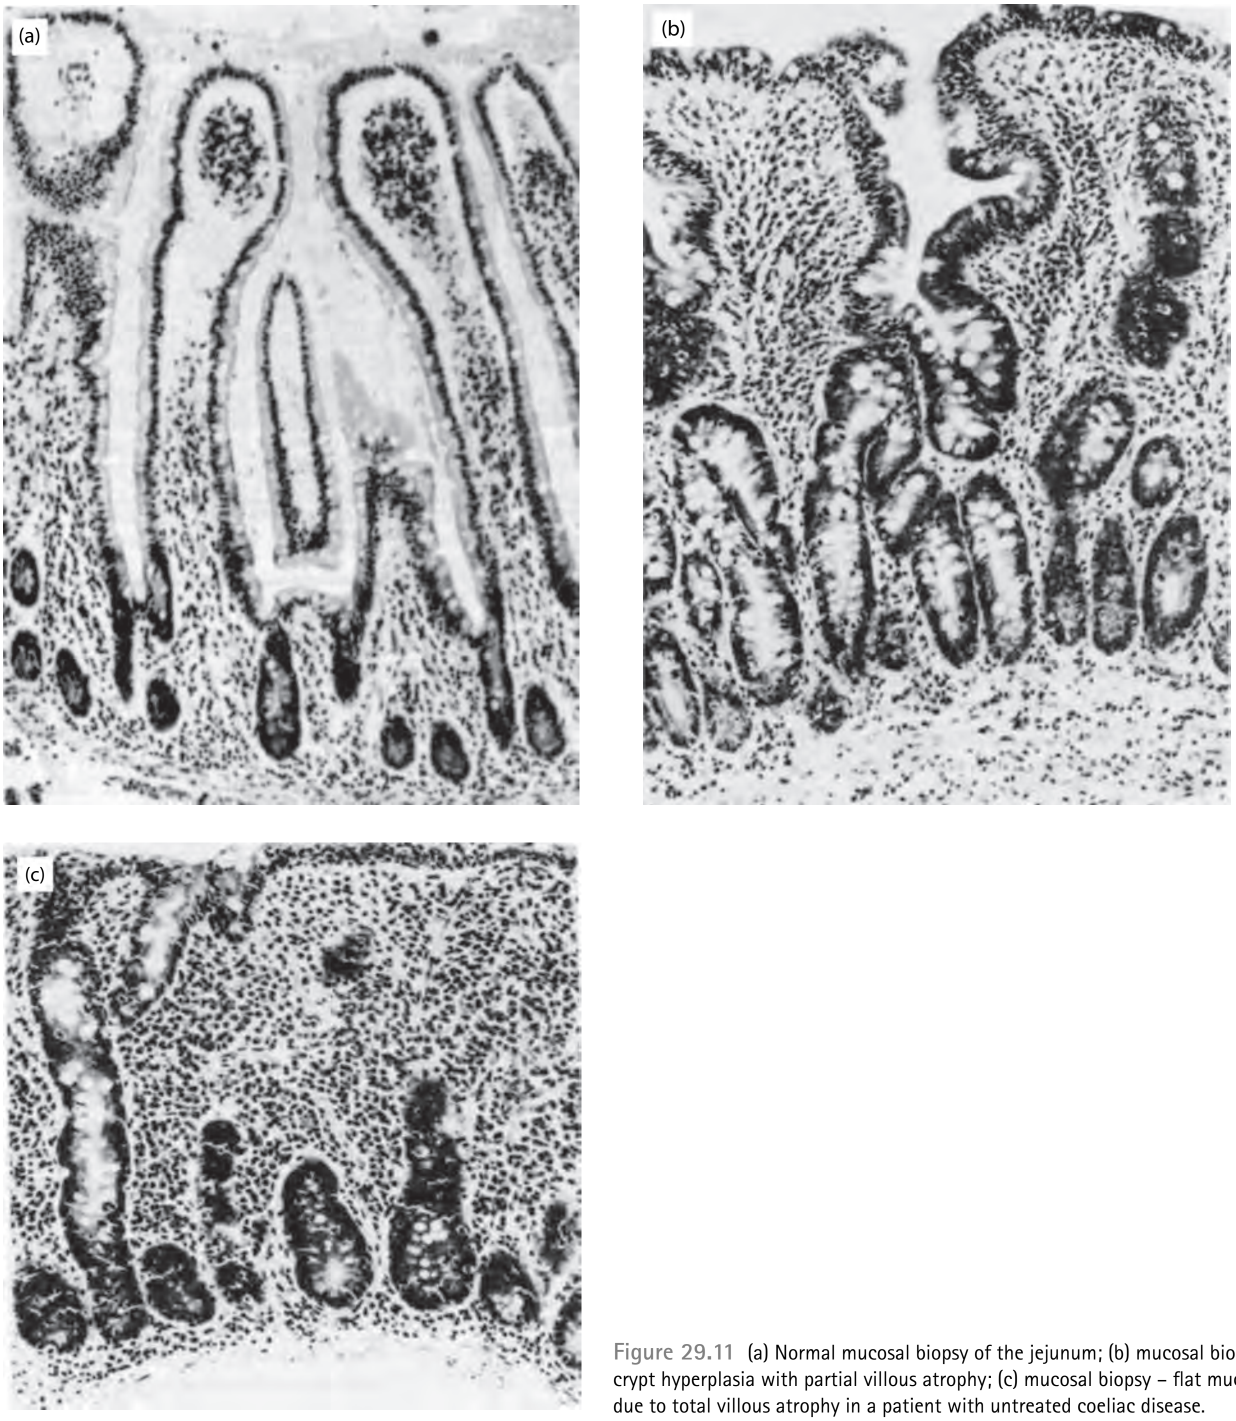

Figure 29.11 (a) Normal mucosal biopsy of the jejunum; (b) mucosal biopsy – crypt hyperplasia with partial villous atrophy; (c) mucosal biopsy – flat mucosa due to total villous atrophy in a patient with untreated coeliac disease.

reaches the caecum the resulting bacterial fermentation induces a sustained rise in the breath hydrogen concentration (Figure 29.15). Strictly speaking, the test measures the oral–caecal transit time, which includes the gastric emptying time. However, if the meal is radiolabelled with technetium both gastric emptying and small bowel transit times can be calculated from a single investigation.

In patients with bacterial overgrowth the fasting hydrogen concentration in the expired breath is elevated. In addition, there is an early rise in the hydrogen in the expired air following the administration of the lactulose.

Tests of intestinal permeability

Various disorders including Crohn's disease and mucosal enteropathies are associated with abnormal permeability of the intestinal mucosa to macromolecules that are not absorbed by the intact normal mucosa. The methods used to test permeability are based on the absorption of substances

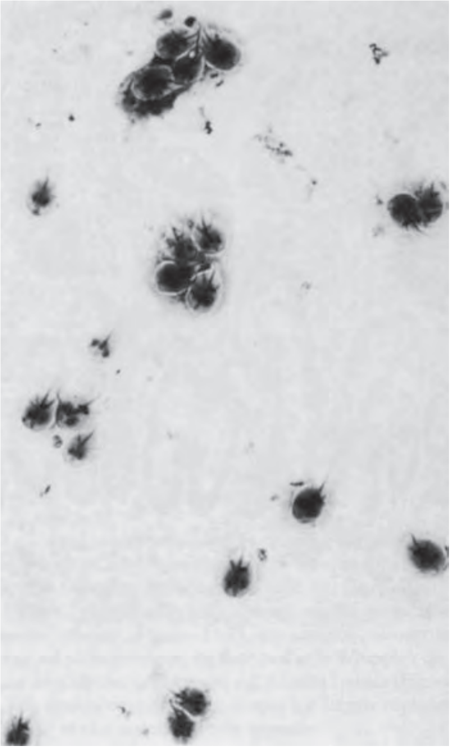

Figure 29.12 *Giardia lamblia* obtained from a jejunal mucosal biopsy.

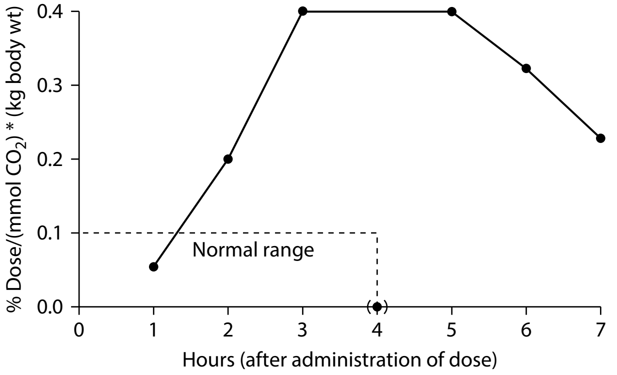

Figure 29.13 ^{14}C-glycocholate breath test in a female patient with weight loss, hypoproteinaemia and moderate steatorrhoea. The investigation is clearly abnormal with an increased amount of labelled CO_2 being detected in the expired air. Normally less than 0.1% of the administered dose is recovered in the expired breath. The patient had an ileotransverse anastomosis for Crohn's disease. The bacterial overgrowth subsided when the excluded diseased bowel was resected.

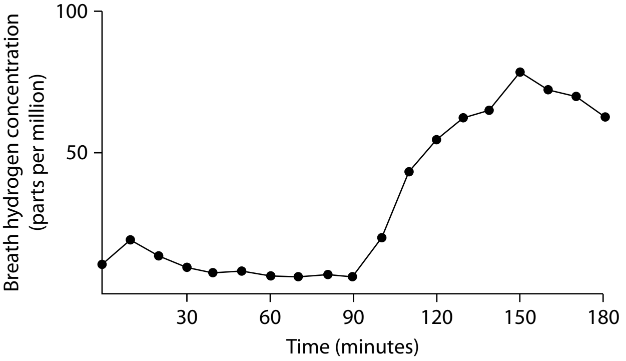

Figure 29.14 Breath hydrogen excretion in a patient with small bowel bacterial overgrowth. Breath hydrogen excretion in a normal subject following 10 g of lactulose. Determination of the oral–caecal transit time by the hydrogen breath test. Following the administration of lactulose solution, serial H_2 estimations are performed on samples of end-expiratory air. A sustained rise in the H_2 in the expired air indicates that the head of the meal has reached the caecum where bacterial fermentation of the non-absorbable carbohydrate occurs.

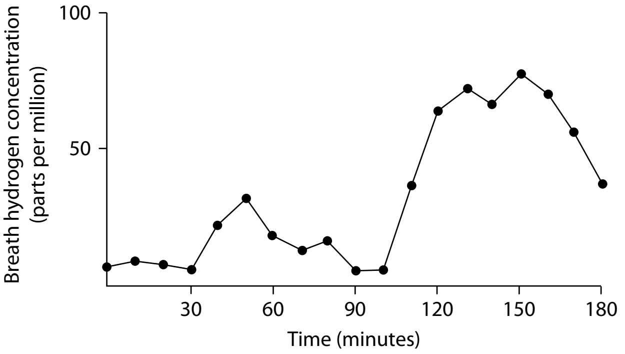

Figure 29.15 Breath hydrogen excretion in a patient with small bowel bacterial overgrowth. Breath hydrogen excretion in a normal subject following 10 g of lactulose. H_2 lactulose breath test in a patient with bacterial overgrowth. The fasting H_2 in the expired air is high and there is an early rise in the breath H_2 after the ingestion of the lactulose solution.

that are normally excluded and if absorbed (because the gut permeability is pathologically enhanced) are not biodegraded and can thus be detected in the blood or urine. Clinically the pathological absorption of these substances is detected by analyses of urine samples for the specific agent used in the test. Examples of test substances include polyethylene glycol 400 and combinations of small and large compounds with differential absorption, e.g. mannitol and cellobiose. When differential studies using two substances are used, the abnormal permeability is demonstrated by changes in the ratio of the urinary concentrations of high- to low-molecular-weight test compounds. The oral administration of ^{51}Cr-labelled EDTA can be used as a quick non-invasive test of abnormal mucosal permeability.

Small bowel neoplasia

Small bowel tumours are rare and collectively account for less than 10% of all gastrointestinal neoplasms. The majority (70%) of small bowel neoplasms are benign and include epithelial tumours (adenomas), lipomas, haemangiomas, gastrointestinal stromal tumours (GISTs) and neurogenic tumours. A number of gastrointestinal disorders are associated with an increased risk of invasive malignancy. These include Crohn's disease, coeliac disease, dermatitis herpetiformis and radiation enteritis. Additionally, invasive malignant transformation occurs with certain polyposis syndromes (see below).

Benign small bowel tumours

Many benign small bowel tumours remain asymptomatic throughout life. Others present either with gastrointestinal bleeding or with intestinal obstruction, most commonly due to intussusception. This should be distinguished from idiopathic intussusception, which commonly occurs in children under the age of 2 years. Tumour-induced intussusception occurs later than the idiopathic variety and does not usually reduce by hydrostatic treatment. Chronic blood loss from a benign small bowel tumour causing iron deficiency anaemia is a fairly common presentation of small bowel tumours and the more vascular tumours may give rise to acute severe gastrointestinal bleeding. If available, small bowel CE has replaced most other investigative tests in patients with this presentation. Otherwise, the diagnosis may be made by small bowel follow through or small bowel enema or, in the case of vascular tumours, by mesenteric angiography. In patients presenting with intestinal obstruction, the diagnosis is usually established at emergency laparotomy. Benign small bowel tumours may be single or as multiple.

Surgical excision of small bowel tumours is the standard treatment. Exploratory laparotomy with total excision of the lesion provides the safest treatment and material for establishing a definite diagnosis, especially for lesions which may be malignant. Tumours discovered incidentally during laparotomy for surgical treatment of other symptomatic disease should be removed and subjected to detailed histological examination. Certain lesions discovered because of occult bleeding may be treated endoscopically with the double or single balloon operating endoscope. Acute life-threatening bleeding may be managed by angiographic embolization with open surgery in reserve should embolization fail. All patients who develop intestinal obstruction are managed with emergency laparotomy. Segmental resection and enterotomy/polypectomy can be used depending on the extent and pathology of the disease. If the pathology cannot be established at the time of resection, full segmental resection with adequate margins is recommended.

Hyperplastic polyps

These are benign mucosal single or multiple lesions occurring in the duodenum, jejunum and proximal ileum. The duodenal lesions are frequently discovered by routine upper gastrointestinal endoscopy. Hyperplastic polyps are generally asymptomatic with no malignant potential. They may be removed endoscopically with biopsy forceps or with the single or double balloon endoscope if situated further distally.

Adenomas

There are of three types: (1) adenomatous polyps, (2) Brunner gland adenomas and (3) villous adenomas. All may be single or multiple, and sessile and pedunculated. Histologically, they appear as intraluminal extensions of the mucous membrane and submucosa with multiple acini supported on a central fibrovascular core. Varying degrees of differentiation are encountered with the various types. Adenomas may cause obstruction, bleeding, intussusception and, occasionally, malignant degeneration, particularly with larger villous lesions. Brunner gland adenomas develop most often along the posterior wall of the duodenum at the junction of the first and second parts and may be single, multiple or diffuse. Histologically, they exhibit benign proliferation of the Brunner glands with scattered ductal and stromal elements.

Villous adenomas are rare and most frequently found in the duodenum. They may give rise to bleeding or obstruction, and as with their counterparts in the colon and stomach, they may be associated with malignant degeneration. Villous adenomas larger than 4.0 cm are at particular risk of developing or harbouring malignancy.

Mesenchymal tumours

These include GISTs, true gastrointestinal smooth muscle tumours (GISMTs) and neurogenic tumours. GISTs are identified on the basis of their immunohistochemical staining characteristics. All are positive for c-Kit (CD117) and CD34 and although some GISTs show positive staining for muscle actin, all are negative for desmin and S100 protein. With all mesenchymal tumours, the distinction between the benign and malignant forms is often difficult. In general however malignant tumours are larger, more often ulcerated and exhibit marked cellularity and necrosis. The tumour can be confidently labelled as benign only if the patient is disease free for at least 3 years after surgical excision. Smooth muscle tumours may occur anywhere in the small intestine but are more commonly found in the jejunum and ileum.

Gastrointestinal stromal tumours or gut stromal tumours

GISTs are the most common mesenchymal neoplasms of the gastrointestinal tract and can also originate in the mesentery and omentum. Overall, however, GISTs are rare, with a lower prevalence than adenocarcinomas and lymphomas of the gastrointestinal tract. They may form intraluminal or extraluminal or transmural (dumbbell-shaped) tumours.

The term GIST was coined by Mazur and Clark in 1983, as these tumours do not exhibit the ultrastructural and immunohistochemical features characteristic of smooth muscle. Instead, they are thought to originate from pluripotential mesenchymal stem cells which normally differentiate into the interstitial cell of Cajal (gastrointestinal pacemaker cells, responsible for initiating and co-ordinating gastrointestinal motility), hence the alternative name suggested by Kindblom *et al.* of ‘GI pacemaker cell tumours’. GISTs can occur anywhere in the gastrointestinal tract. They originate as submucosal tumours which usually grow endoluminally in the affected viscus, although instances of GISTs with predominant extraluminal growth are well documented. At the time of diagnosis GISTs range in size from 1 to 40 cm and above. The stomach is the most common site of origin (50–70%) followed by the small intestine (20–30%). Less frequent sites include the colon and rectum (5–15%), oesophagus (<5%) and very rarely duodenum, omentum and intestinal mesentery. GISTs have a tendency to surface ulceration and deep necrosis, giving rise to severe acute bleeding (the most common presentation of GIST), although minor occult bleeding from surface erosion may occur and give rise to iron-deficiency anaemia. Other complications of GIST include bowel obstruction, intussusception and tumour perforation. Differentiation between benign and malignant GISTs can be difficult even on histological examination.

Molecular biology studies have led to the reclassification of GISTs as distinct tumours separate from smooth muscle tumours, and provided information on their molecular pathogenesis, which, in turn, has led to newer more effective medical therapy based on inhibition of tyrosine kinases as these tumours are largely unresponsive to conventional chemotherapy.

Aetiology and pathology

Mutations in exon 11 of the c-*kit* proto-oncogene are associated with most GISTs. These mutations cause overexpression and autophosphorylation of c-Kit, inducing a cascade of intracellular signalling that stimulates cell proliferation. The *c-kit* proto-oncogene is located on chromosome arm 4q11–12. It encodes KIT, which is a transmembrane tyrosine kinase. Stem cell factor acts as the ligand for KIT. Under normal circumstances, KIT activation occurs when stem cell factor binds to the extracellular domain of c-Kit resulting in homodimerization of the normally inactive c-Kit monomers. The resulting autophosphorylation of intracellular tyrosine residues exposes the binding sites for the intracellular signal transduction molecules with activation of a signalling cascade that involves phosphorylation of several downstream target proteins, including MAP kinase and RAS. Following signal transduction to the nucleus, marked mitotic activity and protein transcription ensue.

Although some families with hereditary GISTs have been described, the majority of cases are sporadic. One of these rare familial types is characterized by multiple GISTs with or without the presence of dermal and mucous membrane hyperpigmentation, multiple naevi and urticaria pigmentosa, mast cell dysfunction and diffuse hyperplasia of gastrointestinal spindle cells. GISTs occur with a higher than expected frequency in patients with type 1 neurofibromatosis and in patients with the rare *Carney triad* (epithelioid gastric stromal tumours, pulmonary chondromas, and extra-adrenal paragangliomas), which usually affects young females.

On histopathological examination, three types of GISTs are recognized: spindle cell (70%), epithelioid cell (20%) and mixed types (10%), with the spindle cell type being particularly difficult to differentiate from smooth muscle tumour although these lack c-Kit immunoreactivity. The Fletcher *et al.* histological classification of GISTs is useful as it differentiates between very low-, intermediate- and high-risk tumours with corresponding different prognosis: 5 year survival rates of 34% for high-risk tumours and 63% for the low-risk groups (Table 29.2).

Table 29.2 Fletcher *et al.* histological classification of gastrointestinal stromal tumours

	Size (cm)	**Mitotic count/50 HPFs**
Very low risk	<2	<5
Low risk	2–5	<5
Intermediate risk	<5	6–10
	5–10	<5
High risk	>5	>5
	>10	Any
	Any	>10

HPF, high-power fields

The pathology report should also include predominant cell type, extent of nuclear pleomorphism, extent of tumour, distance from resection margins and lymph node deposits. The most common sites of metastatic disease from malignant GISTs are the liver (71%) and peritoneum (53%).

Clinical features

The reported incidence of GISTs is one to two per 100 000 per annum. The age incidence of GISTs is 55–65 years, although they may occur in young adults. Most GISTs are diagnosed when they are less than 4.0 cm in diameter, frequently as an incidental finding during endoscopic or radiological investigations or during elective or emergency surgery for gastrointestinal haemorrhage or intestinal obstruction. Lesions greater than 5.0 cm in diameter are more likely to cause symptoms which include:

- non-specific abdominal pain or discomfort
- early satiety or a sensation of abdominal fullness
- rarely, a palpable abdominal mass
- obstruction: from intraluminal growth of an endoluminal tumour or intussusception induced by a small submucosal tumour or from extrinsic luminal compression by an exophytic lesion. The obstructive symptoms can be site-specific: dysphagia (oesophageal GIST), acute small bowel obstruction (jejunoileal GIST), constipation/chronic obstruction (colorectal GIST), obstructive jaundice (duodenal GIST)
- gastrointestinal haemorrhage: from pressure necrosis and ulceration of the overlying mucosa
- perforation with acute peritonitis: usually from tumours of the stomach and small intestine. The perforation may be silent and localized with late presentation as an intra-abdominal abscess
- symptomatic anaemia in patients with recurrent occult blood loss: malaise, fatigue or exertional dyspnoea
- in some patients the tumour is discovered during investigation for an unrelated disorder or as an unexpected finding during emergency surgery for acute bleeding or perforated viscus.

In the absence of complications or large symptomatic tumours (palpable abdominal mass), the physical examination is usually negative as there are no physical findings to specifically suggest the presence of a GIST. Some patients present with physical findings associated with gastrointestinal blood loss, bowel obstruction, bowel perforation and abscess formation.

Surgical treatment

It is important to stress that the optimum management of GISTs requires close participation between the surgeon and medical oncologist. Despite the recent advances in tyrosine kinase inhibitor therapy, surgery remains the definitive therapy for patients with GISTs as radical and complete surgical excision offers the only chance for cure. Surgical treatment may also be indicated in symptomatic patients with locally advanced or metastatic disease, since debulking of large tumours improves the response obtained with adjuvant imatinib mesylate therapy. In patients presenting with acute complications (major gastrointestinal bleeding, intestinal obstruction, peritonitis), resuscitation and stabilization is followed by emergency surgical intervention. Hepatic artery embolization and chemoembolization may also be considered in patients with imatinib-resistant tumours with progressive liver metastases.

There is growing evidence that the laparoscopic surgical approach should be considered for the resection of gastric GISTs. In a seminal study by Novitsky *et al.*, 50 consecutive patients undergoing laparoscopic resection of gastric GISTs were identified in a prospectively collected database. Outcome measures included patient demographics and outcomes, operative findings, morbidity and histopathological characteristics of the tumour. Patient and tumour characteristics were analysed to identify risk factors for tumour recurrence. The patients underwent 47 local and three segmental laparoscopic gastric resections. Mean tumour size was 4.4 cm with the majority of the lesions located in the proximal stomach. The mean operative time was 135 minutes, the average blood loss was 85 mL and the mean length of hospitalization was 3.8 days. There were no major perioperative complications and no mortality. All the resections had negative resection margins. At a mean follow-up of 36 months, 46 (92%) patients were disease free, one patient was alive with disease, one patient with metastases died of a cardiac event and two (4%) patients died of metastatic disease. No local or port site recurrences were identified. Patient age, tumour size, mitotic index, tumour ulceration and necrosis were statistically associated with tumour recurrence. As reported in other series, the presence of 10 or more mitotic figures per 50 high-power fields (HPFs) was an independent predictor of disease progression.

Medical treatment

Conventional systemic chemotherapy is not effective in GISTs and has largely been replaced by tyrosine kinase inhibitors. Intraperitoneal chemotherapy with cisplatin and doxorubicin or mitoxantrone is nowadays used as salvage therapy in patients resistant to tyrosine kinase inhibitor therapy. GISTs are radioresistant, and for this reason radiotherapy is not indicated. The only effective, specific, cytotoxic is imatinib mesylate (Gleevac). This is a selective tyrosine kinase inhibitor with action against mutant c-Kit. Druker *et al.* first reported promising response rates following therapy with imatinib in patients with chronic myeloid and acute lymphoblastic leukaemia. This was followed by several phase II clinical trials with imatinib including a large series of patients with GISTs reported by Blanke *et al.* involving 145 patients. Although in this study no complete responses were observed,' partial clinical response was obtained in 59% of patients on treatment with imatinib in doses of 400–600 mg per day. A subsequent series reported by van Oosterom *et al.* on 35 patients with GISTs treated with imatinib in doses of 400–1000 mg per day obtained partial response rates in 54%, and disease stability with no progression in a further 37%. The most common side effects reported by patients are periorbital and peripheral oedema, fatigue, skin rash and nausea and vomiting. At 10 months of follow-up, 82% of patients maintained the partial clinical response or showed no evidence of disease progression. However, subsequent studies with longer follow-up have shown that, despite the initial efficacy, many patients develop drug resistance to imatinib mesylate. The most effective dose of imatinib mesylate remains unknown pending results of randomized prospective clinical trials. The current recommended dose in adult patients is 400 mg orally q.i.d. with food.

Sunitinib (Sutent) is a multikinase inhibitor that targets several tyrosine kinases implicated in tumour growth, angiogenesis and metastatic progression. It inhibits platelet-derived growth factor receptors (PDGFR-α and -β), vascular endothelial growth factor receptors (VEGFR1, VEGFR2 and VEGFR3), stem cell factor receptor (KIT), Fms-like tyrosine kinase-3 (FLT3) and colony-stimulating factor receptor type 1. Sunitinib is indicated in patients with GISTs in whom the disease has progressed or who are resistant or unable to tolerate treatment with imatinib. The reported clinical studies show that it delays median time to tumour progression. The adult dose is 50 mg orally q.i.d. for 4 weeks with a rest for 2 weeks before the cycle is repeated. Other tyrosine kinase inhibitors known to be effective in leukaemias are currently being tested for their efficacy in patients with advanced GISTs unresponsive to Gleevec and Sutent.

Prognosis

The prognosis depends on extent of the disease (localized primary vs metastatic/recurrent disease) and, in particular, on the histopathological features of the tumour. Hence the overall 5-year survival rate varies widely from 25% to 65%. Larger GISTs are associated with complications, e.g. gastrointestinal haemorrhage, gastrointestinal obstruction and bowel perforation. Individual tumours are classified into high- and low-risk categories based on size and mitotic activity. In the published literature benign GISTs are generally two to three times more common than the malignant counterparts. Histological features suggestive of malignancy include large tumour cell size, lack of cellular differentiation and more than 10 mitotic figures per 50 HPFs (see Fletcher *et al.* classification).

Gastrointestinal smooth muscle tumours

Although smooth muscle tumours may affect other organs such as the uterus and urinary bladder, etc., only GISMTs are considered here. In the past prior to advances in molecular oncology, many GIST tumours were misdiagnosed as GISMTs. It is now established that these tumours are much rarer than

GISTs, with an estimated relative frequency of one GISMT for 36 GISTs. By definition on histology, the component tumour cells resemble smooth muscle with visible, often fibrillar and eosinophilic cytoplasm, usually in long bundles or fascicles. The nucleus is long and oval, often with a cytoplasmic vacuole and indistinct nucleoli. In addition, there is some deposition of collagen between smooth muscle cells, which may resemble myofibroblasts (less cytoplasm, smaller nuclei with dense chromatin). Histochemistry with trichrome stain colours the smooth muscle cytoplasm red and the collagen blue or green. All GISMTs are negative on testing for c-Kit immunoreactivity.

GISMTs are rare constituting only 1% of gastrointestinal tumours, but they occur with an increased incidence in immunocompromised patients (AIDS, transplanted patients and congenital immune deficiency disorders) compared with the general population, as all these patients are at risk of immunosuppression-associated malignancies which include smooth muscle tumours. In these immunodeficient patients, smooth muscle tumours are strongly associated with the immune dysregulation caused by the Epstein–Barr virus (EBV).

Most GISMTs are benign (leiomyomas, ≤5 mitoses per 50 HPFs) but some (14–14%) are malignant (leiomyosarcomas, ≥35 mitoses per 50 HPFs). GISMTs can occur in the oesophagus and rectum, but the commonest site is the stomach (body and antrum) and they are less common in the small intestine. Some are asymptomatic and discovered as incidental findings during investigation of an unrelated disorder. The clinical presentation in symptomatic patients depends on tumour location, but vague abdominal pain and gastrointestinal bleeding are the usual presenting symptoms. Complete surgical excision is the treatment of choice and is always curative for leiomyomas. Leiomyosarcomas do not respond to radiotherapy or chemotherapy. The only effective treatment is therefore surgical excision with a wide healthy margin together with the regional lymph nodes and associated mesentery. The prognosis after resection of leiomyosarcoma is however poor with frequent local recurrence and metastases mainly to the liver leading to death in at least 50%

Lipomas

Small bowel lipomas are benign submucosal tumours of mesenchymal origin. These tumours are often located in the ileum and may frequently develop as pedunculated or sessile submucosal lesions. They may grow undetected to a size sufficient to produce symptoms of colicky abdominal pain and intermittent bowel obstruction. Intussusception may be produced by pedunculated lipomas. Histological features include collections of mature adipose tissue and fibrous tissue strands. Evidence of surface ulceration, central necrosis and haemorrhage may be present. Collections of adipose tissue may be found near the ileocaecal valve. These deposits must be differentiated from genuine small bowel lipomas.

Intra-abdominal neurogenic tumours

Although they involve other intra-abdominal organs and spaces much more often than the small intestine, neurogenic tumours are conveniently discussed here. They are broadly classified into:

- nerve sheath tumours: neurilemmomas, neurofibromas, neurofibromatosis
- tumours arising from ganglion cells: ganglioneuromas, ganglioneuroblastomas, neuroblastomas
- tumours arising from the paraganglionic system: phaeochromocytomas, paragangliomas.

By far neurofibromas are the commonest and may be solitary or multiple and associated with systemic neurofibromatosis and café-au-lait skin patches (*von Recklinghausen disease*). Intra-abdominal neurogenic tumours are most commonly located in the retroperitoneum, in the paraspinal regions and in the adrenal glands, although rarely they can occur in other sites, e.g. urinary bladder, bowel wall, gallbladder and abdominal wall. All intra-abdominal neurogenic tumours with the exception of neuroblastomas and ganglioneuroblastomas present in adult patients. On CT, neurogenic tumours have a distinctive appearance as smooth or lobulated masses, often with areas of calcification. In the absence of distant metastases, the differentiation between benign and malignant lesions is often difficult. In suspect lesions, special imaging modalities such as MRI and positron emission tomography scanning may be necessary for characterization, extent of tumour and related staging. The mainstay of treatment of intra-abdominal neurogenic tumours is surgical excision irrespective of type, provided there is no evidence of distant metastases on the preoperative work-up. The resection can be carried out laparoscopically except for large or frankly malignant lesions.

Nerve sheath tumours

These include neurilemmoma, neurofibroma, neurofibromatosis, and neurogenic sarcoma (malignant schwannoma). More than 90% of nerve sheath tumours are benign and usually present in young and middle-aged adults with a female–male incidence of 2:1. Nerve sheath tumours are multiple in 10% of cases.

Neurilemmomas (schwannomas) arise from the nerve sheaths of peripheral nerves as encapsulated lesions with the nerve fibres stretched over and around the tumour. Although they may occur anywhere, they have a predilection for the head and neck region and the flexor surfaces of the limbs. However, they may develop as internal lesions of the retroperitoneum, where they account for 6% of primary tumours of this space and in the posterior mediastinum.

Retroperitoneal tumours are usually located in the paravertebral region adjacent to the kidney or in the presacral space. At presentation, neurilemmomas are usually less than 5.0 cm in diameter, but much larger lesions may present in the retroperitoneal space. These tumours often have areas of central necrosis due to inadequate blood supply with cyst formation, calcification, haemorrhage and hyalinization. Histologically, neurilemmomas consist of two different components: Antoni types A and B. Antoni type A areas are highly cellular and composed of spindle cells, whereas in Antoni type B areas the tumour cells are separated by abundant oedematous fluid, often forming cystic spaces. They present in young to middle-aged adults, with females being affected twice as often as males. The vast majority of these tumours are asymptomatic and hence discovered incidentally. The CT appearance is that of a well-demarcated round or oval mass often with cystic degeneration and calcification (punctate, mottled, or curvilinear along the periphery of the lesion).

Neurofibromas and neurofibromatosis

About 90% of neurofibromas are solitary. The rest occur as part of von Recklinghausen disease. On histology, they consist of proliferation of nerve sheath cells interspersed with thick collagen bundles and may exhibit variable myxoid degeneration. Unlike neurilemmomas, neurofibromas are not encapsulated and do not exhibit a clear partition into Antoni A and B areas. Additionally, neurofibromas are solid tumours and seldom exhibit gross cystic change, although they may undergo myxoid degeneration with formation of multiple small cysts. Neurofibromas may undergo malignant degeneration, particularly in cases of neurofibromatosis, whereas neurilemmomas seldom, if ever, undergo malignant degeneration.

Neurofibromas occur more frequently in men than in women usually in the second to fourth decades of life. On CT scanning they have a homogeneous, smooth, round appearance with a well-defined outline.

The term neurofibromatosis comprises a group of heterogeneous disorders that include two distinct types:

- NF-1 neurofibromatosis
- NF-2 neurofibromatosis: bilateral acoustic schwannomas and multiple meningiomas (central neurofibromatosis).

NF-1 is an inherited disorder, which predominantly affects the skin and peripheral nervous system and is characterized by the presence of café-au-lait spots and neurofibromatous nodules along the peripheral nerves (*von Recklinghausen disease*) (Figure 29.16).

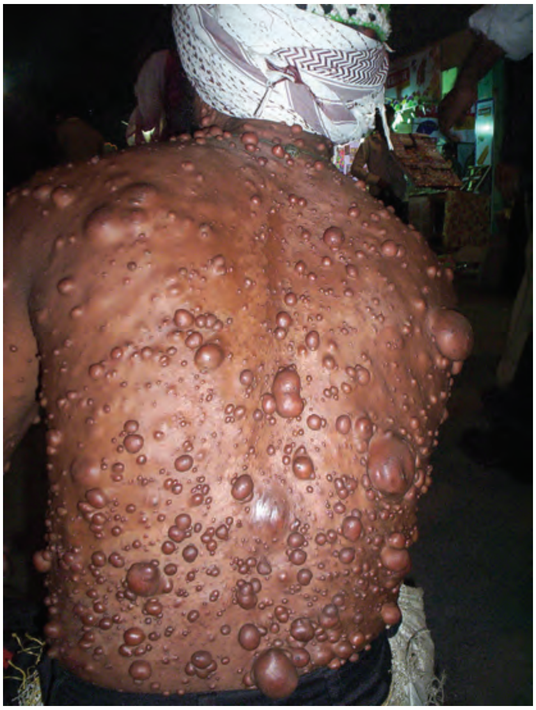

Figure 29.16 NF-1 neurofibromatosis (von Recklinghausen disease). (Courtesy of Professor Omar Shah Srinagar, Kashmir India.)

These extracranial tumours may be solid or plexiform neurofibromas. Approximately 30% of patients with solitary neurofibroma have NF-1, and virtually all patients with multiple neurofibromas or plexiform neurofibromas have NF-1. The abdominopelvic manifestations of NF-1 may involve numerous intra-abdominal ganglia and plexuses, which innervate the abdominal and pelvic organs. These tumours tend to arise in the retroperitoneal, mesenteric and paraspinal regions. Plexiform neurofibromas within the pelvis may form large, infiltrating masses in the presacral or gluteal regions. In contrast, the hallmarks of NF-2 are bilateral vestibular schwannomas and multiple meningiomas. NF-2 rarely demonstrates CNS involvement.

Malignant nerve sheath tumours

Malignant nerve sheath tumours may be encountered in patients with or without neurofibromatosis, but malignant lesions arising in the absence of neurofibromatosis are commoner. Malignant lesions have an equal sex incidence, with the majority arising in adults aged 20–50 years. Differentiation from benign tumours by preoperative imaging tests is unreliable, although irregular borders and lack of homogeneity of the mass are suggestive but inconclusive. More reliable signs of malignancy include large size, bilateral lesions and attenuation by parapsoas masses and their progressive enlargement on serial CT scans. Pain is also common in malignant tumours.

Tumours of ganglion cell origin

These include benign ganglioneuroma, malignant neuroblastoma and ganglioneuroblastoma, the latter exhibiting an intermediate biological aggressive behaviour. The adrenal gland is the most common primary site of these tumours. Neuroblastoma and ganglioneuroblastoma usually occur in infants and children, whereas ganglioneuroma usually affects adolescents and young adults.

Ganglioneuromas

Ganglioneuromas are rare benign tumours arising from sympathetic ganglia. They are composed of mature Schwann cells, ganglion cells and nerve fibres. Ganglioneuromas may arise anywhere along the paravertebral sympathetic chain and occasionally from the adrenal medulla. However, the two most common are the retroperitoneum (32–52%) and the posterior mediastinum (39–43%). They may also occur in the cervical region. In the abdomen, ganglioneuromas occur either in the retroperitoneum (60%) or in the adrenal gland (40%). Although the tumours can occur at any age, the majority affect children and young adults (50%). Ganglioneuromas are often asymptomatic even when large. Otherwise, the clinical features include abdominal pain and a palpable abdominal mass. Hormonally active lesions secreting catecholamines, VIPs or androgens with associated hypertension, diarrhoea and virilisim are well documented. The CT or magnetic resonance scan shows a retroperitoneal or adrenal well-circumscribed tumour which may be oval or lobulated. These tumours tend to partially/completely surround major blood vessels but without narrowing the lumen. Additionally, ganglioneuromas exhibit heterogeneous contrast enhancement. One of the imaging characteristics of ganglioneuroma on MRI is curvilinear bands of low signal intensity on T_2 weighted images, giving the tumour a whorled appearance. The prognosis is excellent, and recurrence is rare after surgical resection.

Ganglioneuroblastomas and neuroblastomas

Ganglioneuroblastomas contain elements of both malignant neuroblastoma and benign ganglioneuroma. Histologically they behave as malignant lesions and contain a mixture of primitive neuroblasts and mature ganglion cells. The most common site of origin is the abdomen, followed by the mediastinum, neck and lower extremity. Macroscopically ganglioneuroblastomas are frequently encapsulated and contain granular calcification. Ganglioneuroblastomas usually occur in children aged 2–4 years with an equal sex incidence and are exceedingly rare after the age of 10. Their CT appearances vary, ranging from a predominantly solid mass to a predominantly cystic mass. Their prognosis and response to treatment are significantly better than neuroblastomas.

Neuroblastomas are malignant tumours consisting of primitive neuroblasts. They may arise anywhere within the sympathetic chain or adrenal medulla. On histology they are composed of small, dark neuroepithelial cells that may show glial or ganglionic differentiation and contain nests of primitive round cells with dark-staining nuclei and scanty cytoplasm. Clinically, they usually present during the first 10 years of life (80% occur in children <5 years) and are commoner in boys. Seventy per cent of neuroblastomas are intra-abdominal, with the majority originating from the adrenal gland. The remaining intra-abdominal abdominal/pelvic tumours originate from the paravertebral sympathetic chain or presacral area, and occasionally from the coeliac axis. Neuroblastomas tend to metastasize to bone, bone marrow, liver, lymph nodes and skin. Unfortunately, 70% of patients have metastatic disease at the time of diagnosis. Neuroblastomas may invade adjacent organs or encase blood vessels.

Both on plain radiography and CT, neuroblastomas usually contain areas of coarse calcification. Both CT and MRI scans are useful for preoperative assessment of extent of tumour and staging: involvement of retroperitoneal lymph nodes and hepatic deposits, tumour encasement of vessels and into the vertebral canal.

Tumours of the paraganglionic system

The paraganglionic system includes the adrenal medulla, the chemoreceptors (carotid and aortic bodies), vagal body, and the small groups of cells associated with the thoracic and intra-abdominal and retroperitoneal ganglia. Tumours that arise from the chromaffin cells of the adrenal medulla are called phaeochromocytomas or chromaffinomas, whereas those that occur in paraganglia at other sites are referred to as paragangliomas. On investigation, phaeochromocytomas are found to be the cause in 0.1–0.5% of patients with newly diagnosed hypertension. These tumours occur with equal frequency in men and women and usually present in the third and fourth decades. Phaeochromocytomas have been called '10% tumours' because 10% are bilateral, 10% are extra-adrenal (paragangliomas of the retroperitoneum, mediastinum or urinary bladder), 10% occur in children and 10% are malignant. When they occur in children, there is often a family history. Phaeochromocytomas may be associated with multiple endocrine neoplasia (MEN) 2a and 2b or 3 syndrome, von Hippel–Lindau syndrome and neurofibromatosis (NF-1, von Recklinghausen disease). MEN 2a syndrome consists of phaeochromocytoma, medullary carcinoma of the thyroid gland and parathyroid hyperplasia, whereas MEN 2b or 3 syndromes consist of phaeochromocytoma, medullary carcinoma of the thyroid gland, ganglioneuromatosis, and multiple mucosal neuromas. Phaeochromocytomas associated with MEN syndrome tend to be bilateral and are almost always intra-adrenal and usually benign.

The clinical manifestations of phaeochromocytoma result from excess and inappropriate secretion of catecholamine. The classic triad of headache, palpitation and excessive sweating is seen during the paroxysmal hypertensive crisis. Urinary metanephrine or vanillylmandelic acid levels are elevated in over 90% of patients. Confirmation by urinary 24 hour catecholamine excretion studies is followed by CT scanning of the adrenal gland. If no lesion is found in the adrenal, further CT studies are needed of the organ of Zuckerkandl (all chromaffin cell-bearing tissue along the lower abdominal aorta from the origin of the inferior mesenteric artery to the aortic bifurcation) and the urinary bladder (common site of paraganglioma). At CT, both phaeochromocytomas and paragangliomas are usually 3.0 cm or larger and demonstrate areas of necrosis or haemorrhage. Phaeochromocytomas are hypervascular and exhibit marked contrast enhancement after intravenous administration of contrast. If no lesion is found on CT and laboratory test results are positive on repeat testing, radionuclide imaging with meta-iodo-benzylguanidine (MIBG) may identify a small occult lesion. MRI can also be used to help locate a small paraganglioma.

Spontaneous rupture of a phaeochromocytoma or paraganglioma will produce a dramatic acute clinical presentation with severe hypovolaemic shock from massive retroperitoneal haemorrhage and severe back pain, not dissimilar to ruptured abdominal aortic aneurysm.

In general, paragangliomas exhibit a more aggressive behaviour than adrenal phaeochromocytomas. Thus 20–40% of paragangliomas metastasize, as opposed to 2–10% for adrenal phaeochromocytomas. Spread via the lymphatics and blood is to regional lymph nodes, bone, liver and lung.

Polyposis syndromes involving the small bowel

These syndromes are characterized by a common pathological feature – the presence of multiple polyps which may affect all regions of the gastrointestinal tract. Individually, each syndrome is distinguished by its aetiology (genetic or otherwise), the microscopic appearance of the polyps and the risk of invasive malignancy. The four polyposis syndromes which involve the small intestine are:

- familial adenomatous polyposis (FAP)
- Peutz–Jeghers syndrome (PJS)
- generalized juvenile polyposis
- Cronkhite–Canada syndrome (CCS).

Familial adenomatous polyposis

This hereditary autosomal dominant condition is characterized by the development of multiple adenomatous polyps in the colon and which inevitably progress to invasive colonic cancer (see Chapter 30). Additionally, however, some 80% of patients with FAP also have adenomas involving the small bowel and, like the colonic polyps, these are also premalignant. They tend to occur mainly in the duodenum in the region of the ampulla of Vater (second part). In patients with FAP who have had their colon removed, the most common cause of cancer death is from periampullary cancer. When found, large duodenal adenomas in FAP patients should be removed surgically or endoscopically. There is some evidence that certain anti-inflammatory agents may reduce the growth of some of these small bowel adenomas in FAP colectomized patients. However, surveillance by flexible endoscopy or CE is advisable in all these patients every 2 years.

Peutz–Jeghers syndrome

This is an autosomal dominant disorder consisting of mucocutaneous pigmentation (on the face, lips and buccal mucosa) and benign gastrointestinal hamartomas. The polyps are found in the small bowel in up to 90% of affected individuals but the polyps can also be in the stomach and colon. The hereditary defect is associated with mutation of the *LKB1* gene (19p2, 3). Complications are common and include colicky abdominal pain, gastrointestinal bleeding, intestinal obstruction and the development of gastrointestinal and various extraintestinal cancers.

Aetiology and pathology

PJS is characterized by intestinal hamartomatous polyps in association with mucocutaneous melanocytic macules. The cause of PJS appears to be a germline mutation of the serine threonine kinase (*STK11)* gene, which is present in the majority of patients. This protein is regulated by phosphorylation by cAMP-dependent protein kinase A. *STK11/LKB1* (serine/threonine kinase 11) is a tumour suppressor gene (overexpression induces growth arrest of cells at the G1 phase of the cell cycle) located on band 19p13.3. Somatic inactivation of the unaffected allele of *STK11* is frequently present in polyps and cancers from patients with PJS. The variable penetrance of the gene accounts for the varied phenotypic manifestations encountered clinically in patients with PJS: different number and location of polyps and different pigmentation patterns. Although other genes may be involved in the aetiology of PJS, the current evidence is that *LKB1* defects are the major cause of PJS, although other mechanisms may be involved. Adnab-9, which is a premalignant marker found in Paneth cells, is more common in PJS than in familial juvenile polyposis and hyperplastic polyps. Thus Adnab-9 labelling may identify polyps at higher risk of malignant degeneration.

Histologically, the polyps of PJS exhibit a distinctive frond-like appearance with a stromal/smooth muscle core covered by acinar glands and normal mucosa without any nuclear atypia. The number, as well as the size and the location, of the polyps vary from patient to patient. Isolated melanotic mucocutaneous pigmentation without gastrointestinal polyps has also been described and is explained by the genetic variability of the syndrome.

The principal cause of morbidity in PJS results from the intestinal location of the polyps (small intestine, colon, stomach). Complications, which usually occur in the second and third decades, include small bowel obstruction and intussusception (43%), gastrointestinal bleeding (14%) and rectal prolapse of a colonic polyp. Almost 50% of patients with PJS develop and die from cancer by the age of 60, with the mean age at first diagnosis of cancer being 43 years. The cumulative risk for the development of specific cancers is as follows: breast 54%; colon 39%; pancreas 36%; stomach 29%; ovary 21%; lung 15%; small intestine 13%; cervix 10%; testes 9%; and uterus 9%. The statistically significant elevated relative risk (RR) and confidence intervals (CI) for cancer in the various organs relative to the general population is as follows:

- all cancers (RR 15.2; CI 12–19)
- oesophagus (RR 57; CI 2.5–557)
- stomach (RR 96; CI 96–368)
- small intestine (RR 520; CI 220–1306)
- colon (RR 84; CI 47–137)
- pancreas (RR 132; CI 44–261)
- lung (RR 17; CI 5.4–39)
- breast (RR 15.2; CI 7.6–27)
- uterus (RR 16.0; CI: 1.9–56)
- ovary (RR 27; CI 7.3–68).

Clinical features

PJS is rare, with a reported frequency of three per 300 000 population, i.e. approximately one-tenth that of FAP. The sex incidence is equal. The average age at diagnosis is 23–26 years. The clinical features of PJS include a family history, repeated bouts of abdominal pain and obscure intestinal bleeding in patients younger than 25 years, rectal prolapse, menstrual irregularities in females (due to hyperostrogenism), gynaecomastia in males (oestrogens production from Sertoli cell testicular tumours) and precocious puberty. Small bowel obstruction develops in about 50% of patients. The obstruction may be caused by the polyp itself or result from intussusception initiated by a polyp.

Physical examination shows mucocutaneous pigmentation and melanin spots are present in more than 95% of patients. The pigmented lesions are present in the first years of life and may fade at puberty with the exception of lesions on the buccal mucosa which persist in all cases. The pigmented lesions consist of small, flat, brown or dark blue spots/macules (1–5 mm) resembling freckles, most commonly in the circumoral and perinasal area. The pigmentation may also be present in the fingers and the toes, on the dorsal and volar aspects of the hands and the feet and around the anus and genitalia. A rectal mass (rectal polyp) or a large polyp can prolapse outside the anus.

Treatment

There is no specific medical therapy. PJS should be diagnosed as early as possible and genetic counselling provided. Screening for both intestinal cancers and extraintestinal cancers should be implemented once the diagnosis is established. This includes an annual physical examination of the breasts, abdomen, pelvis and testes. Surveillance for cancer has been suggested with small bowel enema every 2 years (and, more recently, CE), upper gastrointestinal endoscopy, colonoscopy every 2 years, annual ultrasound scanning of the pancreas, pelvis (in women) together with cervical smears (Papanicolaou) and examination of the testes in males. Mammography is advised at 25, 30, 35 and 38 years and thereafter every 2 years until age 50. In addition, all haemorrhagic or polyps >5 mm should be removed by endoscopic polypectomy

Surgical treatment is reserved for complications: intestinal obstruction (including intussusceptions), resection of large polyps, persistent gastrointestinal bleeding and the development of invasive cancers.

Generalized juvenile polyposis

Generalized juvenile polyposis can be inherited or sporadic. The polyps can arise anywhere in the intestinal tract. They have a distinctive microscopic appearance and can bleed or cause intestinal obstruction when large. The risk of invasive gastrointestinal cancer is however small. Juvenile gastrointestinal polyposis is a syndrome described in infants who present with hamartomatous polyposis, macrocephaly, alopecia, nail dystrophy, clubbing of fingers and toes, hypotonia, hepatosplenomegaly, anaemia and hypoproteinaemia due to protein-losing enteropathy. Although some authors consider this syndrome a form of CCS, others think it is a different entity. The prognosis is usually very poor.

Cronkhite–Canada syndrome

CCS, first described by Cronkite and Canada in 1955, is characterized by intestinal polyps, pigmentation, diarrhoea and protein-losing enteropathy, which may lead to severe weight loss from malnutrition, dystrophic changes in the fingernail, alopecia and abdominal pain. The polyps are most commonly found in the small intestine and usually do not become malignant. CCS is not familial. The aetiology is uncertain, although an autoimmune process is thought to be responsible. Thus many patients have elevated antinuclear antibody (ANA) and immunoglobulin (Ig)G4 levels. Other suggested aetiological factors include mental stress and physical fatigue. The disease is very common in the Japanese, who form 75% of the reported cases. The estimated incidence of CCS is one per million. The mean age of onset is in the fifth to sixth decade, with a slight male predominance. Endoscopically, the gastric mucosa may be thickened with hypertrophic gastric folds mimicking Ménétrier disease or be atrophic with polypoid lesions. The colonic polyps in CCS are usually sessile with a ‘strawberry-like’ appearance.

Pathophysiology

The gastrointestinal changes consist of a generalized hamartomatous polyposis with abnormal intervening mucosa. The prevalence of gastrointestinal malignancy in patients with CCS is about 10%. The polyps are part of a generalized gastrointestinal mucosal disturbance that results in malabsorption and protein-losing enteropathy leading to severe diarrhoea, abdominal pain and profound malnutrition. Dermatological manifestations accompany the gastrointestinal symptoms. The vast majority of affected individuals have alopecia, alterations in the nail beds and skin pigmentation. Although the published data support the view that ectodermal signs are consequent on the severe malnutrition, this is by no means certain, especially as the ectodermal changes may precede the gastrointestinal symptoms and signs. The aetiology is unknown. Japanese reports have suggested mental stress, family problems and physical fatigue as the most frequent precipitating factors. Patients with CCS often have coexisting autoimmune disorders, e.g. type 1 diabetes, hypothyroidism, membranous glomerulopathy, and high titres of ANA.

A recent report described the infiltration by IgG4 producing plasma cells in 50% of patients with CCS, suggesting it belongs to the group of IgG4-related autoimmune diseases which include autoimmune pancreatitis, sclerosing cholangitis and peritoneal fibrosis.

Clinical features

The disease is commoner in males and in Japan; the male-to-female ratio is 2:1. The age distribution of published cases ranges from 31 to 85 years, with onset of disease occurring most commonly in patients aged 50–60 years. The initial symptom is either diarrhoea or hypogeusia (taste disturbances). Clinically, the disease usually exhibits a rapid progression over several months in the severity of the gastrointestinal symptoms leading to substantial weight loss, malnutrition and peripheral oedema. Ectodermal changes are usually observed several weeks or months after gastrointestinal symptoms begin. Aside from the consequences of malnutrition, which can become life threatening, most of the complications encountered are manifestations of the polyposis. Some patients with CCS present initially with other gastrointestinal disorders including *Helicobacter pylori* gastritis, eosinophilic gastroenteritis and intestinal candidiasis.

The diarrhoea, which is present in 90% of patients, is multifactorial. The intestinal mucosal glands secrete a copious amount of protein-rich fluid. Additionally, diseased small bowel mucosa is unable to digest and absorb disaccharides and triglycerides. Additionally, the normal gut microflora is replaced by bacterial overgrowth. Patients typically have five to seven loose watery bowel movements per day with volumes averaging 4–6 L. Abdominal pain, anorexia, vomiting, weakness and weight loss accompany the diarrhoea and steatorrhoea. Weakness is related to protein calorie malnutrition with muscle wasting, dehydration and faecal electrolyte losses (calcium, magnesium, potassium and zinc).

The morbidity of CCS stems from malabsorption (vitamins, carbohydrates, lipids, vitamins, fluid and electrolyte, and enteric losses of serum proteins), resulting in oedema, congestive heart failure and immunodeficiency. Iron-deficiency anaemia results from chronic blood loss with iron and folate deficiency. Rarely, massive bleeding may occur and prove fatal. The early estimates of a 50% 5 year death rate in patients with CCS have been significantly reduced by improved supportive therapy.

Physical examination reveals characteristic ectodermal changes starting several weeks or months after the initial gastrointestinal symptoms in almost all patients. Most patients have two or more of the cutaneous triad that consists of alopecia (initially patchy but progresses to complete hair loss), nail changes in fingers and toes (onychodystrophy), consisting of thinning, splitting and partial separation of nail from nail bed, and hyperpigmentation, consisting of brownish macules or plaques most commonly on the hands and arms but may occur elsewhere and be widespread.

Treatment

This is essentially supportive with fluid and electrolyte replacement and restoration/maintenance of macronutrient and micronutrient requirements. Mild malnutrition is treated with replacement of fluids and electrolytes using elemental diets, but severe cases of malnutrition require complete bowel rest and total parenteral hyperalimentation.

Antibiotics are administered orally for bacterial overgrowth. Systemic infections are treated with broad-spectrum antibiotics administered parenterally. Hydrocortisone sodium succinate is the most commonly used corticosteroid to decrease inflammation by reversing capillary permeability and suppression of polymorphonuclear cell activity. Other drugs used include proton pump inhibitors for gastric acid suppression, alone or in combination with appropriate antibiotics to eradicate *H. pylori* infection, cromolyn and zinc/vitamin supplements. Sulindac (a non-steroidal anti-inflammatory drug) does not induce regression of CCS polyps. Surgical treatment is reserved for the treatment of complications, i.e. bleeding, obstruction (usually from intussusception) and the development of invasive malignancy.

Malignant small bowel tumours

Malignant small bowel tumours are extremely rare, accounting for less than 5% of all malignant gastrointestinal neoplasms. Several factors have been suggested to explain the rarity of both benign and malignant small bowel tumours. The first explanation relates to the rapid small bowel transit time, which limits contact time of any carcinogen with the small bowel mucosa. The second concerns the large volume and fluid nature of the small bowel content, which dilutes any intraluminal irritant/carcinogen. The third protective factor is attributed to the high pH of the intestinal content associated with the low bacterial colony count of the small bowel. Additionally, the small bowel contains high levels of the enzyme benzpyrene hydroxylase, which destroys potential carcinogens.

The downside to the rare incidence of malignant small bowel tumours is their asymptomatic early phase, such that their clinical presentation is usually with advanced disease with tumour spread beyond the confines of the bowel wall by the time of diagnosis. There are four important malignant small bowel tumours:

- adenocarcinoma (40%)
- carcinoid tumours (30%)
- lymphomas (25%)
- GISTs (5%), discussed previously.

In many cases, diagnosis is usually made at laparotomy for small bowel obstruction. However, increasingly early-stage tumours are being diagnosed by CE. The other diagnostic modalities which may be useful include small bowel follow-through, small bowel enema and small bowel enteroscopy, including single-balloon endoscopy and DBe, mesenteric angiography and CT. In some cases laparoscopic examination of small intestinal loops may be useful and enables biopsy of serosal and mesenteric masses.

Adenocarcinoma

Adenocarcinomas of the small intestine are rare, being 50–60 times less common than colonic adenocarcinoma. They are mucus-secreting tumours and are commonest in the proximal part of the small intestine (duodenum 40%, jejunum 40%, ileum 20%). The majority of duodenal carcinomas are found in the periampullary region and in the third part of the duodenum. Intestinal adenocarcinomas spread primarily to the regional lymph nodes, liver and peritoneal cavity. The prognosis is poor largely because of late presentation, resulting in an overall 5 year survival of 15%. Surgery is the mainstay of treatment as these tumours are largely unresponsive to chemotherapy and radiotherapy.

Aetiology and pathology

The aetiological factors include genetic and environmental risk factors in addition to specific small bowel disorders which predispose to the disease. The genetic conditions include FAP as these patients in addition to colon cancer are at risk of duodenal adenocarcinoma (RR >300). Aside from colorectal carcinoma, patients with hereditary non-polyposis colorectal cancer (HN-PCRC) can also develop other cancers, including small bowel adenocarcinoma (>100 times that of the general population). In these patients, the cancers are distributed evenly throughout the small bowel, occur at younger age and have a better prognosis than sporadic small bowel cancers. The most commonly mutated genes in patients with HN-PCRC are *HMLH1* and *HMSH2*, which are involved in DNA mismatch repair.

Environmental risk factors include high consumption of animal fat, red meat and salt-cured or smoked foods and smoking. Other than FAP and HN-PCRC, the predisposing disorders/conditions for small bowel cancer include the following.

- Crohn's disease: RR variously estimated between 15 and >100. Adenocarcinoma occurs late, usually 20 or more years after the onset of Crohn's disease, and the majority develop in the ileum, reflecting the distribution of the disease.
- Coeliac disease: carries a RR of 300 for the development of lymphoma and 65 for the development of small bowel adenocarcinoma.

- PJS: associated with an 18-fold increase in the incidence compared to the general population.
- Ileostomy sites.
- Surgically bypassed duodenum.
- Jejunal limb of a Roux-en-Y oesophagojejunostomy.
- Ileal segment of a defunctionalized ileocystoplasty.

Pathologically, the tumours are graded as grade I (well differentiated), grade II (moderately differentiated) and grade III (poorly differentiated). Small bowel adenocarcinomas are more common in the upper reaches of the small bowel with 40–50% affecting the duodenum and arising from the mucosa in the region of the ampulla of Vater or from the third part. Periampullary tumours usually form papillary growths. More distal lesions may be polypoid, annular or fungating and often present with acute intestinal obstruction. Small bowel adenocarcinomas produce mucin and, like large bowel cancers, exhibit carcinoembryonic antigen (CEA) reactivity and express COX-2, sPLA2¢ and cPLA2. Endocrine cells (chromogranin and 5-HT) are also present scattered among the adenocarcinoma cells, particularly in ileal tumours. Rarely, these endocrine cells exhibit immunoreactivity for various peptide hormones: somatostatin, YY peptide, neurotensin, glucagon, etc.

Clinical features

In general, men have higher rates of all types of small bowel cancer than females (M/F ratio of 1.4:1.09). The prevalence increases with advancing years, with a mean age at diagnosis averaging 60 years. Small bowel cancer is asymptomatic in its early stages, and hence the majority present with advanced disease. The common presenting symptoms include abdominal discomfort, which is usually postprandial and colicky in nature, nausea and vomiting, particularly in patients with duodenal carcinomas and weight loss. Intestinal obstruction occurs in 50% of patients with the diagnosis being made during emergency surgery. Adenocarcinomas are more frequently associated with pain and obstruction than small bowel sarcomas (including GISTs), which tend to present more commonly with gastrointestinal bleeding. When it occurs, gastrointestinal bleeding may be occult leading to iron-deficiency anaemia but may also be overt leading to melaena or frank rectal bleeding. Intestinal obstruction usually indicates advanced disease, although a relatively small polypoid tumour may lead to intussusception. Patients with periampullary duodenal carcinomas usually present with obstructive jaundice.

The investigations used to establish the diagnosis depend on the clinical presentation. In patients presenting with bleeding, upper gastrointestinal endoscopy and colonoscopy are usually performed in the first instance. Colonoscopy with retrograde ileoscopy may be useful in identifying distal ileal tumours. In the absence of bleeding or acute presentation with small bowel obstruction, small bowel follow-through or small bowel enema (enteroclysis) have been traditionally used for establishing the diagnosis, but are being replaced in many centres with small bowel endoscopy and balloon endoscopy. Although small bowel enteroclysis with the double contrast technique has a sensitivity of 95%, it is difficult to perform and unpleasant for the patient. Plain abdominal X-ray films are indicated in patients presenting with partial or complete small bowel obstruction.

The American Joint Committee on Cancer staging system is generally used for the staging of small bowel malignant tumours.

Primary tumour (T)

- TX: Primary cannot be assessed
- T0: No evidence of primary tumour
- Tis: Carcinoma *in situ*
- T1: Tumour invades the lamina propria or submucosa
- T2: Tumour invades the muscularis propria
- T3: Tumour invades through the muscularis propria into subserosa or into non-peritonealized perimuscular tissue (mesentery or retroperitoneum), with extension of less than 2.0 cm
- T4: Tumour penetrates the visceral peritoneum or directly invades other organs or structures

Regional lymph nodes (N)

- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Regional lymph node metastasis

Distant metastases (M)

- MX: Presence of distant metastasis cannot be assessed
- M0: No distant metastasis
- M1: Distant metastasis

Stage grouping

- Stage 0: is, N0, M0
- Stage I: T1–2, N0, M0
- Stage II: T3–4, N0, M0
- Stage III: Any T, N1, M0
- Stage IV: Any T, any N, M1

Treatment

Surgical resection provides the only hope of cure for patients with small bowel adenocarcinomas. Resection with curative intent or palliative is possible in 70% of cases with the remainder having unresectable disease at the time of presentation because of extensive local disease or metastases to regional lymph nodes, liver and peritoneal serosal surfaces. In patients deemed potentially curable, a wide radical (5.0 cm margins) segmental excision with regional lymphadenectomy is performed. In patients with duodenal adenocarcinoma, this necessitates radical pancreaticoduodenectomy. Tumours close to the ileocaecal valve may require a right hemicolectomy. In published series, 5 year survival rates of 40–60% have been reported with radical surgery. Surgical excision may also be indicated for palliation in patients with symptomatic advanced disease causing intestinal obstruction.

Although various chemotherapy regimens have been used in patients with incurable disease most commonly with 5-fluorouracil (5FU) based regimens, FOLFOX 4 (infusional 5FU, oxaliplatin and leucovorin) and irinotecan, the benefits in terms of response rates and survival benefit have been poor. Similarly the addition of adjuvant chemotherapy after surgery does not improve outcome of patients after surgical resection.

Carcinoid tumours

These are neuroendocrine tumours (NETs) which include *carcinoid tumours* and *pancreatic endocrine tumours*. Carcinoid tumours account for the largest number of NETs and can produce the carcinoid syndrome. NETs originate from enterchromaffin-like cells, which normally control acid secretion by releasing histamine and which also regulate the *motility of the gastrointestinal tract.* The commonest sites of carcinoids of the gastrointestinal tract are the appendix, small intestine and the rectum in that order (see The vermiform appendix section for further discussion of carcinoid tumour of the appendix).

Pathology

Carcinoid tumours arise from the Kulchitsky cells of the crypts of Lieberkuhn. These neuroendocrine cells are also referred to as 'enterochromaffin cells' as they stain with potassium chromate. The aetiology of carcinoid tumours is not known, but genetic abnormalities are suspected. Multiple carcinoid tumours occurring in association with MEN 1 are well documented. Carcinoid tumours which occur predominantly in the gastrointestinal tract are classified into three groups.

- *Foregut tumours* may be sporadic primary tumours or secondary to achlorhydria. Sporadic foregut tumours occur in the lung, bronchus, stomach, proximal duodenum and pancreas. These tumours consist of regularly shaped cells which assume a trabecular arrangement and contain round granules. They exhibit an argyrophilic reaction, which indicates that the cells can only be stained with metallic silver in the presence of a reducing agent.
- *Midgut tumours* arise in the second portion of the duodenum, jejunum, ileum and the right colon. They account for 60–80% of all carcinoid tumours (especially in the appendix and distal ileum) in adults but may also be encountered in children commonly as apical lesions of the appendix, often discovered as an incidental finding in appendicectomy specimens. The tumour cells are pleomorphic and are arranged in nests separated by connective tissue. These cells have both argentaffin (can be stained directly with metallic silver without reducing agent) and argyrophilic staining properties.
- *Hindgut tumours* occur in the left colon and rectum. The cells here are arranged in a trabecular pattern containing round granules but do not stain with silver.

Foregut tumours produce 5-HTP, 5-HT (serotonin), histamine and substance P. Midgut tumours produce 5-HT, kallikrein and prostaglandins. Tumours of the hindgut do not usually secrete active peptides. In addition, midgut and foregut tumours may contain and secrete a variety of hormones including insulin, somatastatin, adrenocorticotrophic hormone (ACTH), gastrin, antidiuretic hormone, parathormone, glucagon, VIP, calcitonin, β-melanocyte-stimulating hormone, cholecystokinin and growth hormone. The cytology and histology cannot differentiate between benign and malignant carcinoid tumours. In general, tumours smaller than 1.0 cm are rarely malignant. Tumours between 1.0 and 1.9 cm may be malignant, and tumours larger than 2.0 cm are usually invasive and may exhibit metastatic spread. These more aggressive lesions invade the bowel wall mesentery, parietal peritoneum and adjacent organs. Metastatic spread involves the regional lymph nodes, peritoneum and liver in particular, but other sites such as the lung, spleen, ovaries and the bones may be affected.

Carcinoid tumours of the duodenum are rare. They tend to be similar in nature to other gastrointestinal carcinoids but there is an unusual type known as the carcinoid islet cell tumour which has the functional, morphological and histochemical features of both foregut carcinoids and pancreatic islet cell tumours (APUdomas). In addition to serotonin, the tumour may also produce and secrete a variety of peptide hormones such as gastrin, insulin, parathyroid hormone and catecholamines causing bizarre clinical manifestations.

Carcinoid tumours of the small intestine are most commonly encountered in the ileum. The majority are malignant, 40% are multiple and in 30% there is an associated malignant neoplasm usually an adenocarcinoma. In the gastrointestinal tract, carcinoids develop deep in the mucosa and with growth they extend into the underlying submucosa, thus forming small firm yellowish grey nodules, which bulge into the intestinal lumen. The yellow colour results from the accumulation of cholesterol and lipids. Carcinoid tumours can have a polypoid appearance and may become ulcerated. With increased invasive growth, they eventually infiltrate the muscularis propria to reach the serosa and the mesentery when they are invariably accompanied by metastatic spread.

Three types of carcinoid tumours are differentiated on histology: (1) classical, (2) tubular adenocarcinoid and (3) goblet cell carcinoids (GCCs). The classical type forms solid nests of small uniform cells with occasional acinar or rosette formation, infrequent mitosis and retraction of tumour periphery from stroma, with some cells being located within intra-appendiceal nerves (may be related to histogenesis). They usually invade the muscularis and may spread to the serosal surface. Ultrastructurally the component cells contain pleomorphic dense-core secretory granules. The tubular (adenocarcinoid) type of carcinoid is characterized by glandular architecture without solid nests and lack mitoses and atypia. The cytoplasmic granules are large and acidophilic. The GCC exhibits a predominantly submucosal growth with frequent extension into muscle and serosa, the mucosa being spared. Some cells may be lysozyme-positive cells with features of Paneth cells. Ultrastructurally the cells contain mucin droplets and neurosecretory type granules at times in the same cell (amphicrine cells). GCCs are discussed further under Carcinoid tumours of the appendix.

In the midgut carcinoid lesions may be associated with diffuse thickening of the bowel wall. Carcinoid tumours commonly affect the tip of the appendix but they often invade the wall of the appendix and spread to the regional lymph nodes, and about 75% of patients have evidence of peritoneal involvement. The high potential for metastasis by carcinoid tumours is thought to be caused by the production and release of β-catenin. The size of the tumour correlates with the stage of the disease; tumours smaller than 1.5 cm are rarely accompanied by distant metastases or recurrence after surgical excision.

Carcinoid tumours can be associated with concentric and elastic vascular sclerosis, which may result in obliteration of the vascular lumen and ischaemia. Fibroblastic proliferation is caused by stimulation of fibroblast cells by growth factor produced by the tumour. Carcinoids often express somatostatin receptors which are used for imaging and treatment of the disease.

Clinical features

Carcinoid tumours are rare. In the USA, the estimated incidence is 1.5 cases per 100 000 individuals. The overall age-standardized incidence rate for male and female populations in England is 0.71 and 0.87, respectively. In Scotland, the incidence rate is 1.17 and 1.36 per 100 000 for males and females, respectively. The average age of reported cases of small intestinal carcinoid is between 45 and 55 years. Duodenal carcinoids may present with vomiting due to obstruction or as an endocrine syndrome. Carcinoids of the jejunum or ileum present with diarrhoea, intestinal obstruction, palpable abdominal mass and, much less commonly, massive gastrointestinal haemorrhage or intestinal infarction.

An early symptom of carcinoid tumours, especially in patients with metastases from midgut tumours, is cutaneous flushing. This typically affects the head and neck. Striking colour changes range from pallor or erythema to cyanosis. Episodes are often associated with an unpleasant warm feeling, itching, palpitations, salivation, lacrimation and diarrhoea. Exercise, stress or certain foods (e.g. cheese) may trigger an attack, although the flushing episodes may also be spontaneous. With time, the duration of the flushing episodes increases and may last hours, and, indeed, some patients develop a constant red/cyanotic discoloration.

Diarrhoea and malabsorption occur in the majority of patients. The stools are frothy and bulky (steatorrhoea). The diarrhoea may or may not be associated with abdominal pain, flushing, and cramps. Wheezing caused by bronchospasm may occur and be accompanied by dyspnoea. Relatively uncommon complaints include joint pain, arthritis, lacrimation, confusion and changes in mental status, ophthalmological findings associated with flushing or secondary to vascular occlusion, retroperitoneal fibrosis, obstruction of ureter, intra-abdominal fibrosis, and male sexual dysfunction. Carcinoid tumours can occur in association with familial or genetic disorders, such as MEN 1 and PJS.

Carcinoid syndrome

The carcinoid syndrome is very rare, produced by less than 10% of all carcinoid tumours and in the majority of cases the primary tumour originates in the small intestine. The syndrome is invariably associated with the presence of extensive hepatic involvement by tumour and the clinical manifestations are the result of inappropriate secretion of 5-HT, 5-HTP, kallikrein, histamine, prostaglandin and ACTH, etc. Production of VIP may produce symptoms similar to those of neuroblastoma and ectopic secretion may produce Cushing syndrome induced by foregut carcinoid tumours. Carcinoid crisis can occur spontaneously or as a response to stress, e.g. anaesthesia or chemotherapy. Symptoms may include intense flushing, diarrhoea, abdominal pain, tachycardia, hypertension or hypotension, altered mental status and coma. This condition can be life threatening, but treatment with somatostatin analogue SMS-201-995 has improved the outcome of patients with carcinoid crisis.

In the absence of carcinoid crises, the characteristic symptoms of the carcinoid syndrome include various types of flushing episodes, intestinal colic and diarrhoea, bronchospasm and hypoproteinaemia. The cutaneous flushing episodes affect the upper part of the body and are accompanied by sweating, itching, oedema, palpitations and hypotension. In time, patients may develop other manifestations including cardiac lesions, pellagra-like skin lesions (photosensitive dermatitis), neurological signs, peptic ulceration and neuralgia. Cardiac lesions are present in up to 60% of patients and are the result of endocardial fibrosis, which tends to involve the right heart, especially the ventricular aspect of the tricuspid valve and associated chordate. Stenosis from fibrosis of the pulmonic valve is less common but involvement of the mitral valve is rare. These cardiac lesions may lead to heart failure.

Biochemical confirmation of the diagnosis of the carcinoid syndrome is achieved by the determination of the urinary metabolite of 5-HT and 5-HTP, 5-hydroxyindole acetic acid. The intravenous administration of 2 μg of epinephrine (adrenaline) results in a typical attack of flushing within 2 minutes of the injection, but this test is no longer used.

Treatment of carcinoid tumours and carcinoid syndrome

Whenever possible, complete surgical excision is the treatment of choice. In small bowel carcinoids, block resection of the tumour with regional lymph nodes is needed. In rectal tumours, endoscopic resection is sufficient for tumours measuring less than 1.0 cm limited to the mucosa, otherwise more extensive sphincter-saving resections are needed. The treatment of appendiceal carcinoids is discussed in the section Carcinoid tumours of the appendix.

For secondary hepatic tumours, surgical ligation of the hepatic artery can potentially deprive the blood supply to the tumour cells and cause necrosis while preserving most of the normal liver cells. However, with time, new blood vessels develop and restore circulation such that the clinical benefit is short lived, and, for this reason, this therapeutic approach is seldom used nowadays. If hepatic metastases are resectable, hepatic surgical resection is the preferred treatment. Resection usually involves hepatic plurisegmentectomies. Intra-arterial infusion of chemotherapeutic agents with chemoembolization of the hepatic artery may also provide effective, albeit short term, relief of symptoms due to hepatic metastasis. Both resection and embolization should be covered with antiserotonin therapy. Arterial embolization is performed percutaneously using a selective angiographic technique whereby the arteries feeding the metastases are blocked by gelatin sponge or human dura mater delivered in an antibiotic-containing solution and followed by steel coils. In addition to antiserotonin therapy these patients must be covered by systemic antibiotics and steroids.

Lesser degrees of palliation can be obtained by chemotherapy. The drugs which have been shown to be useful are doxorubicin, 5FU, dacarbazine, actinomycin D, cisplatin, etoposide, streptozotocin, interferon-α and somatostatin analogues with a radioactive load used singly or in combination. The best results have been reported with prolonged infusion chemotherapy, either through the hepatic artery or a tributary of the portal vein. Prolonged access to the hepatic arterial tree is possible with the use of implantable subcutaneous chambers which have a silicon diaphragm allowing intermittent and prolonged infusions (Figure 29.17).

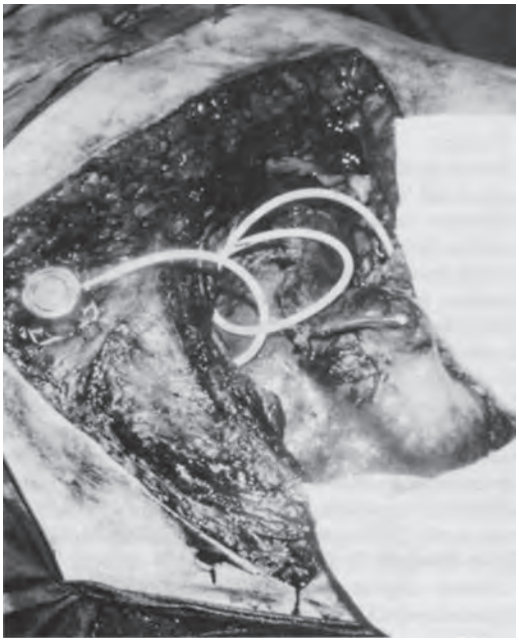

Figure 29.17 Port-A-Cath implantable venous/arterial access system. In this particular patient, the technique has been used for prolonged hepatic arterial infusion chemotherapy for hepatic secondary deposits. In between treatments, the system is left primed with heparinized saline.

Totally implantable infusion pumps are available, but they are expensive and do not have any special advantage over implantable access systems connected to small portable battery power infusion pumps. In the case of metastatic carcinoids, pretreatment with antiserotonin therapy is necessary to prevent a carcinoid crisis during chemotherapy. Antiserotonin therapy can be undertaken with agents that either reduce the production of 5-HT or antagonize its effects (Table 29.3)

Octreotide (synthetic somatostatin analogue) is highly effective in controlling symptoms but without imparting a survival advantage. The best results have been reported with continuous infusions which substantially reduce the plasma insulin-like growth factor I and growth hormone-releasing hormone. The long-acting somatostatin analogue which is administered monthly has removed the need for daily injections/infusions. The adverse effects of prolonged somatostatin therapy include gall stones and steatorrhoea, which may sometimes require pancreatic enzyme replacement. *In situ* targeted therapy with somatostatin analogues (octreotide attached to radioactive yttrium-90 or indium-111) provides promise and is currently undergoing clinical trials in patients with unresectable tumours.

Table 29.3 Antiserotonin drugs and their effects

Parachlorophenylalanin	Relieves diarrhoea
Phenoxybenzamine	Administered to achieve alpha blockade. It may relieve attacks precipitated by emotion, diet, exercise and alcohol
Chlorpromazine	Has antikinin effects and may control flushing
Methysergide maleate	Most potent antagonist of 5-HT. May relieve flushing, diarrhoea and bronchospasm
Cyproheptadine	Less potent antiserotonin agent. May relieve diarrhoea and less frequently reduce intensity of flushing
Prednisolone	May relieve facial oedema, diarrhoea and the flushing symptoms of bronchial carcinoids but not when the symptoms are caused by gastrointestinal tumours
Long-acting somatostatin analogue	Abolishes flushes due to gastrointestinal carcinoids and diarrhoea
Ketanserin	May reduce diarrhoea
Calcitonin	Same effects as somatostatin

5-HT, 5-hydroxytryptamine.

Small bowel lymphoma

Aetiology and pathology

An important distinction must be made between primary intestinal non-Hodgkin's lymphomas (NHLs) and the much more common secondary involvement of the subdiaphragmatic region (abdomen and its viscera) by systemic Hodgkin's nodal or extranodal disease. The agreed criteria for the diagnosis of primary intestinal NHLs are:

- no palpable superficial lymphadenopathy
- no mediastinal lymphadenopathy on chest radiograph/CT
- normal white cell count, normal bone marrow examination
- patients present with gastrointestinal symptoms
- bowel lesion predominates at laparotomy and only regional lymph nodes are involved
- liver and spleen are not involved.

On the basis of these diagnostic criteria, it is likely that in Western countries primary lymphoma accounts for less than 30% of all patients with intestinal involvement by lymphomatous disease. As primary Hodgkin's disease is extremely rare in the gut (1%), for practical purposes all primary intestinal lymphomas are NHLs.

The sites of origin of primary gastrointestinal NHLs are:

- stomach 50–75%
- small bowel 9.0%
- ileocaecal region 7.0%
- involvement of more than one gastrointestinal site 6.0%
- other sites (duodenum, colon, rectum) 3.0%.

Although the exact aetiology of the majority of cases of NHLs of the bowel is unknown, certain predisposing disorders are well documented. These include coeliac disease, ulcerative colitis and Crohn's disease, AIDS and other immunodeficiency states, e.g. transplant patients, chronic lymphatic leukaemia and long-term cyclophosphamide treatment for other forms of malignancy and various infections.

All types of small bowel NHLs are commonest in young adult males (aged 17–53 years) of low socioeconomic class mainly in developing Middle Eastern countries, north and south Africa and the Far East. Immunoproliferative small intestinal disease (IPSID) or Mediterranean lymphoma affects older children and young adults (aged 10–35 years), again in Middle Eastern/Mediterranean countries, although population studies from the Middle East indicate a decline in the incidence of IPSID over the last three decades.

Small bowel NHLs are classified as -cell or T-cell lymphomas, each of which can be further subdivided into low, intermediate and high grade. The majority are -cell lymphomas arising from the centrocyte-like cells of the mucosa-associated lymphoid tissue and referred to as MALT lymphomas. The other common types of intestinal NHLs include the centrocytic lymphomas, Mediterranean lymphoma, Burkitt-type lymphoma and the polymorphic T-cell lymphoma.

The low tendency of small bowel NHLs to disseminate outside the gastrointestinal tract may be due to the expression of specific adhesion molecules and/or dependence on local stimuli such as antigens or chemokines. Mucosal lymphocytes strongly express the $\alpha4\beta7$ integrin, whereas its ligand, MAdCAM-1, is selectively expressed on mucosal endothelium. This explains the established expression of the mucosal homing receptor $\alpha4\beta7$ by mucosa-associated B-NHLs (e.g. low-grade MALT lymphomas and mantle zone lymphomas). Additionally, intestinal epithelial cells produce several chemokines, i.e. CLL25 (TECK), CCL5 (RANTES) etc. The receptors for these chemokines are expressed by $\alpha4\beta7+$ T-lymphocytes present in the lamina propria and in the epithelium. The chemokine CLL25 (TECK) has been shown to attract IgA-secreting cells to the intestine. The chemokine receptor CXCR3 is expressed by a small subset of peripheral -cells and low-grade MALT lymphoma, splenic marginal zone lymphoma and -cell chronic lymphocytic leukaemia (B-CLL). Thus, expression of adhesion molecules and chemokine receptors determines homing and dissemination of both normal and malignant -cells.

Staging of small bowel lymphoma

It is recommended that all new patients with NHLs should have their tumours classified in the first instance according to the World Health Organization (WHO) classification (Table 29.4).

Thereafter, the specific therapy in the individual patients is formulated after clinical staging with the modified Ann Arbor system taking into consideration the International Prognostic Index for the individual patient. Appropriate clinical staging includes a careful history and physical examination; CT or MRI of the chest, abdomen and pelvis; blood chemistry; full blood count; and bone marrow biopsy. The basic staging and investigation for a patient with NHL includes all these studies. Patients at high risk of CNS involvement should have a lumbar puncture for cytology of cerebrospinal fluid.

The details of the Ann Arbor staging system and the Cotswold modifications are shown in Table 29.5.

The Ann Arbor staging system does not provide reliable prognostic information for many subtypes of NHLs and is thus insufficient on its own for the formulation of the treatment regimen in the individual patient. The International Prognostic Index (IPI) is nowadays used for all types of NHLs to individualize prognosis and treatment. The reported studies with the IPI have identified factors which predict the outcome of treatment:

- age greater or less than 60 years
- Ann Arbor stages I and II vs stages III or IV
- none or one vs two or more sites of extranodal involvement by lymphoma
- Eastern Cooperative Oncology Group performance status of grade 0 or 1 vs grade 2 or greater
- a normal vs elevated lactate dehydrogenase (LDH).

The bad predictors of outcome identified by the IPI are:

- age >60 years
- performance status >2
- LDH 1 × normal
- extranodal sites >2
- stage III or IV.

As the adverse prognostic factors have the same prognostic weighting, they are added giving a score of 0–5. The individual

Table 29.4 World Health Organization classification

β-cell lymphomas	**T/NK-cell lymphomas**
Precursor β-cell	**Precursor T-cell**
B lymphoblastic	T lymphoblastic
Mature (peripheral) β-cell	**Mature (peripheral) T-cell**
Diffuse large β-cell lymphoma*	Peripheral T-cell lymphoma
Follicular lymphoma*	Not otherwise specified
Small lymphocytic lymphoma (CLL)	Angioimmunoblastic T-cell lymphoma
	Extranodal nasal NK/T-cell lymphoma
Extranodal marginal zone β-cell lymphomas of the MALT type*	Enteropathy-type T-cell lymphoma
Nodal marginal zone β-cell lymphoma	Hepatosplenic gamma-delta T-cell lymphoma
Splenic marginal zone β-cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
Lymphoplasmacytic lymphoma	Anaplastic large T-/null-cell lymphoma
Burkitt's lymphoma	Mycosis fungoides/Sézary syndrome
	Adult T-cell lymphoma/leukaemia

*Account for more than 50% of non-Hodgkin's lymphomas.
CLL, chronic lymphocytic leukaemia; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

Table 29.5 Ann Arbor staging system and the Cotswold modifications

Stage	**Features**
I	Involvement of a single lymph node region or lymphoid structure (e.g. spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph regions or structures on both sides of the diaphragm
IV	Involvement of extranodal site(s) beyond that designated E
For all stages	
A	No symptoms
B	Fever (>38°C), drenching sweats, weight loss (10% body weight over 6 months)
For stages I–III	
E	Involvement of a single, extranodal site contiguous or proximal to known nodal site
Cotswold modifications	
Massive mediastinal disease has been defined by the Cotswold meeting as a thoracic ratio of maximum transverse mass diameter greater than or equal to 33% of the internal transverse thoracic diameter measured at the T5/6 intervertebral disc level on chest radiography	
The number of anatomic regions involved should be indicated by a subscript (e.g. II_3)	
Stage III may be subdivided into: III_1, with or without plenic, hilar, coeliac or portal nodes; III_2, with para-aortic, iliac, mesenteric nodes	
Staging should be identified as clinical stage (CS) or pathologic stage (PS)	

patient is categorized on this score into one of four groups: (1) low risk (score of 0 or 1), (2) low to intermediate risk (score of 2), (3) high intermediate group (score of 3) and (4) high risk (score of 4 or 5). The published data on the response rate and outcome of patients demonstrate the importance of the IPI scoring (Table 29.6).

Clinical features

Small bowel lymphoma may occur at any age except in infancy, but the peak incidence is in the sixth decade. A smaller peak is encountered in the first to third decades. In general, small bowel NHLs are commoner in males, with a reported sex ratio of 2:1. The presentation may be acute or insidious. In both the Middle East and the West these diseases may present as a surgical emergency with intestinal obstruction or a perforation leading to peritonitis (6–8%). The intestinal obstruction may be due to intramural obstruction by a circumferential lesion or intussusception. The latter is particularly likely to occur with the ileocaecal tumours of childhood.

The most common presenting symptom of small bowel NHLs is pain in the abdomen (80%). Other presenting symptoms include change in bowel habits [diarrhoea or constipation (15%), palpable abdominal mass (15%) and blood in the stool (15%)]. The most common site of the disease is the terminal ileum or ileocaecum (40%) with the rest distributed at various other sites of the small intestine, with some patients (10%) having multifocal areas of involvement. Some patients (5%) give a history of Crohn's disease.

In addition to abdominal pain, the chronic manifestations include malaise, weight loss and anaemia. The anaemia may be normochromic (chronic disease) or hypochromic microcytic (chronic occult bleeding). The erythrocyte sedimentation rate (ESR) is elevated and hypoproteinaemia is frequently present and results from a protein-losing enteropathy. In patients with coeliac disease the enteropathy-associated lymphoma tends to occur in the fifth to the seventh decade. The symptoms of coeliac disease previously controlled by dietary management return and the patients complain of abdominal pain and diarrhoea with rapid weight loss. Perforation leading to peritonitis is a common presentation in these patients.

In the Middle East, IPSID is associated with growth retardation, malabsorption, bacterial overgrowth, hypoproteinaemia with oedema and ascites, and various parasitic infestations. It can also present with intestinal obstruction, perforation and massive haemorrhage. In all cases the commonest physical finding is a mobile abdominal mass.

Table 29.6 Relation between IPI score, response rate and survival

Risk	IPI score	Complete response (%)	Overall 5 year survival (%)
Low	0–1	87	73
Low/intermediate	2	67	51
Intermediate/high	3	55	43
High	>4	44	26

IPI, International Prognostic Index.

Diagnosis

The diagnosis is usually established by means of a small bowel contrast enema, although in recent years small bowel capsule and single-balloon endoscopy DBe or are being used more often. The advantage of balloon endoscopy lies in the provision of biopsy for histological characterization of the lesion. Other investigations used for establishing diagnosis include abdominal ultrasound, CT and MRI scanning and diagnostic laparoscopy. In cases presenting acutely (obstruction/perforation), the diagnosis is made at emergency laparotomy. In IPSID the abnormal α-chain is detected by immunocytochemistry of tumour sections and by immunoelectrophoresis with monospecific IgA antibody of serum and duodenal juice.

Treatment

NHLs are often treatable and frequently curable. However, the choice of the most appropriate therapy in the individual patient requires accurate diagnosis and a careful staging evaluation. New patients with NHL should have their tumours classified using the WHO classification. Patients are then assigned an anatomic stage using the Ann Arbor system and individually scored by the IPI.

Nonetheless, the treatment of gastrointestinal lymphoma is not standardized and there have been few clinical trials. All patients presenting with acute abdominal disease require surgical intervention, and whenever possible the disease should be resected. Further treatment is then administered soon after recovery from the operation. This may consist of combination chemotherapy with drug regimens that are commonly used in Hodgkin's disease (CHOP, CMOPP, etc.) or radiotherapy. Radiotherapy is used less frequently as it is no more effective than chemotherapy and carries a high morbidity (bleeding and perforation).

In uncomplicated lymphoma, surgery followed by chemotherapy or radiotherapy is used for stage I and stage II of the disease. Chemotherapy alone is used for more advanced disease, but the prognosis in these cases is extremely poor. Complete remissions have been reported in patients with IPSID whose biopsy shows plasmacytic infiltration after treatment with tetracycline or cytotoxic drugs, but patients with established lymphoma are generally treated as outlined above. There is no role for surgical treatment in patients with malignant lymphomatous polyposis because of the widespread nature of the lesion, and reliance is placed on effective combination therapy.

Combined-modality therapy (surgical resection followed by chemotherapy) in patients with intermediate- or high-grade disease has resulted in improved survival rates. Chemotherapy reduces recurrence rates and metastatic disease outside the abdominopelvic cavity. Resection remains the initial treatment as it establishes the exact diagnosis (type and grade of the lymphoma), reduces the tumour burden, relieves the symptoms and prevents potential perforation. The role of radiation therapy remains controversial because of its potential morbidity. However, several reported series have shown good tolerance to radiotherapy, although most agree that it is not indicated in patients in whom complete resection has been achieved, as these patients do not derive any benefit from additional abdominopelvic radiotherapy over postoperative chemotherapy alone. In the last 10 years significant advances have been made in the systemic treatment of NHLs, which include the use of humanized monoclonal antibodies, such as rituximab, either alone or more usually with conventional chemotherapy. In some types of lymphomas, exemplified by follicular NHL, they have drastically improved cure rates.

Specific intestinal NHLs

MALT lymphomas

Mucosa-associated lymphoid tissue (MALT) lymphomas occur in a variety of organs, including the orbit, conjunctiva, salivary glands, skin, thyroid gland, lungs, stomach (most common site) and intestine. MALT lymphomas occur at a frequency of about 1.5 per 100 000 people per year in the USA and account for about 10% of all NHLs but the incidence in Western countries varies considerably depending on the prevalence of infection by *H. pylori*, genetic, dietary and environmental factors. Thus in certain regions of Italy, the frequency of MALT lymphomas is about 13 per 100 000 people per year. *Campylobacter jejuni* infection is associated with small bowel MALT lymphomas. The other infections associated with MALT lymphomas include *Borrelia burgdorferi*, *Chlamydophila psittaci* and hepatitis C virus.

Also known as extranodal marginal zone lymphomas, these are mostly low-grade tumours (predominantly small cell) with a tendency to remain localized for long periods and to metastasize late to other sites of MALT. The marginal zone of the B-follicle represents a well-defined compartment of the -cell area with a distinct cellular composition from that of the follicle centre (follicular -cells), from which it differs in its functional role in the immune response. Some tumours have a prominent large cell component. These are high-grade tumours and carry a less favourable prognosis. Microscopically the low-grade tumours form well-defined growths with deep invasion of the bowel wall and are usually single, whereas the high-grade tumours involve extensive segments of the bowel and form large strictured lesions with a tendency to ulceration. Histologically the reactive -cell follicles of the normal lymphoid tissue of the gut are surrounded and infiltrated by neoplastic small to medium -cells with an irregular nuclear contour, which resemble centrocytes. These tumours also form a characteristic 'lymphoepithelial lesion' when the neoplastic centrocyte-like cells invade and damage the crypt epithelium.

Eradication using a triple anti-*H. pylori* regimen in gastric MALT stage IE tumours achieves a complete response in approximately 60–90% of patients. Patients with tumours that are T4 node positive or tumours with adverse cytogenetics should receive radiotherapy or surgery with or without radiotherapy (see Chapter 23). High-grade lesions or large cell tumours with a minor low-grade MALT component are treated with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisone) chemotherapy. This is also used in patients in whom eradication therapy against *H. pylori f*ails. Disseminated MALT lymphomas are incurable and are treated primarily with palliative chemotherapy.

Centrocytic lymphoma (mantle zone lymphoma)

Centrocytic lymphoma is an intermediate-grade lymphoma. Originally thought to arise from small cleaved cells in the germinal centre, subsequent immunological studies have indicated an origin from mantle zone CD5+ B-lymphocytes producing IgM and/or IgD. Genuine cases of centrocytic lymphoma express the *bcl*-1 oncogene. In the recent classification, centrocytic lymphoma is placed in the category of diffuse small cleaved cell myelorid lymphoma and is often referred to as intermediately differentiated lymphocytic lymphoma or as mantle zone lymphoma. The pattern of growth is usually diffuse, often with a follicular appearance.

Mantle zone lymphomas account for 15% of primary intestinal lymphomas. They form superficial diffuse lesions which do not invade the bowel wall deeply, resulting in a convoluted appearance of the mucosa, suggesting multiple polyps, and hence the alternative descriptive clinical name of malignant lymphomatous polyposis. As opposed to other -cell tumours, surgical excision is not appropriate and the treatment is by chemotherapy. Another feature which distinguishes these primary gut tumours is the development of a centrocytic leukaemia and peripheral lymphadenopathy in most patients.

Mediterranean lymphoma

This affects mainly young adults with almost equal sex incidence and involves predominantly the proximal small intestine and is usually associated with chronic diarrhoea and abdominal pain. In 1978, the WHO recommended the term IPSID for the syndrome associated with Mediterranean lymphoma because at that time the disease, especially in its early stages, was not considered to be a truly malignant lymphoma. Many of the patients with IPSID syndrome were found to have variable levels of abnormal immunoglobulin in the serum or other body fluids, which were identified subsequently as truncated heavy chains, hence the alternative synonym of heavy-chain disease (HCD).

The diseased mucosa shows a heavy plasma cell and B-lymphocyte infiltration. The abnormal plasma cells secrete a fragment of IgA (α or heavy chain), which can be detected in the plasma and duodenal juice of affected patients. In some patients suffering from IPSID a malignant -cell lymphoma develops. The initial uncertainty regarding the nature of IPSID (benign disease which undergoes subsequent malignant change) has been resolved by subsequent molecular genetics studies which have confirmed the abnormal *Ig* gene rearrangement in both IPSID and Mediterranean lymphoma, indicating that IPSID is in fact a neoplastic condition. The WHO classification does not recognize the so-called 'non-secretory' IPSID as a specific entity. This variant is characterized by the proliferation of small centrocyte-like lymphoid cells lacking the plasmacytic differentiation observed in the secretory form of HCD. Both 'secretory' and 'non-secretory' forms are common in the same geographic area.

The aetiology remains unknown, although there is good circumstantial evidence for the involvement of various infective agents and their toxins and parasitic infestation, which account for the regional incidence of the disease. As *C. jejnui* has been isolated from patients with IPSID who respond dramatically to treatment by antibiotics, the current hypothesis is that continuous antigenic stimulation within the gut due to *C. jejuni* infection induces the proliferation of IgA-producing plasma cells in the lamina propria of the small intestine.

Patients with IPSID have an acquired immune deficiency (humoral and cellular) and usually have low serum Ig levels. This deficiency and the subsequent development of IPSID have been attributed to the modulatory effects of *Vibrio cholerae* toxins acquired during the epidemic that swept the same IPSID geographic areas during the early 1960s.

Infestations with various parasites (*Ascaris lumbricoides*, *Giardia lamblia*, *Strongyloides stercoralis*, *Trichuris trichiura*) can cause mutations in -cells with their consequent development and differentiation into aberrant plasma cells producing truncated heavy chain proteins. Continuing proliferation of these aberrant cells within the mucosa gives rise to the clinicopathological picture of HCD and eventual progression to the full-blown lymphomatous phase of IPSID. Genetic factors may be involved as evidenced by the association of IPSID with human leucocyte antigens (HLAs) AW19, A9 and B12, and the blood group B. Genetic predisposition is further substantiated by the development of IPSID in relatives living apart from patients with the disease. Occult defects of the cellular and humoral immunity have been detected in first-degree healthy relatives of patients with IPSID. However, it is difficult to be certain whether these observations indicate a genetic predisposition or are the result of shared environmental factors.

The macroscopic features of Mediterranean lymphoma are highly variable and range from diffuse thickening of the upper small intestine with enlargement of the associated mesenteric lymph nodes to localized, often multiple tumours. The histological features vary according to the stage of disease. Initially there is a diffuse infiltration of lamina propria by malignant plasma cells (stage A). Thereafter aggregations of centrocyte-like -cells (stage B) and immunoblasts (stage C) appear and the picture becomes polymorphic. Although often extensive, Mediterranean lymphoma tends to remain confined until the late stages of the disease.

Burkitt-type lymphoma

There are two types of this primary high-grade -cell lymphoma: African or endemic, and sporadic or non-African type, which occurs in Western countries. In both types, the diagnosis is made on biopsy.

The primary gene involved in 90% of patients with Burkitt's lymphoma is the c-*myc* oncogene. It usually results from a translocation of genetic material between the long arm of human chromosomes 8 and 14; less commonly the translocation involves chromosomes 2 and 22 or chromosomes 2 and 8. The c-*myc* oncogene appears to stimulate another gene, the *HMG-I/Y* gene, which then triggers the neoplastic transformation of the -cells. Burkitt's lymphoma is also associated with certain oncogenic viruses, specifically the EBV in endemic Burkitt's and HIV in the sporadic form. Currently, however, the precise role of EBV in Burkitt's lymphoma is still being investigated, because the virus is less common in patients outside Africa. In the USA, about 25% of children and 40% of adult AIDS patients with Burkitt's have the EBV.

The endemic or African type was first described in 1956, by an Irish surgeon (Dennis Burkitt) working in central Africa. The disease, which is very common in children (average age 7–8 years) who are infected with the EBV and usually suffer from chronic malaria infections, is a non-Hodgkin's -cell lymphoma. It is thought that the EBV reduces the resistance and thereby leads to the malignant transformation of the infected -cells. Endemic Burkitt's lymphoma is responsible for 50% of cancer deaths in children in Uganda and central Africa. The disease is characterized by rapid enlargement of the patient's jaw, loosening of the teeth, protruding eyeballs, or abdominal, renal or ovarian tumours.

The sporadic or non-African type of Burkitt's lymphoma which occurs in other countries is also common in children. In this form of the disease, which is more common in males, the EBV infection is acquired because of reduced immunity. These children may present with a facial tumour but much more commonly (90%) with an abdominal mass in the right lower quadrant (ileocaecal region), pain, vomiting and ascites. Involvement of the bone marrow with thrombocytopenia leads to bleeding episodes and anaemia. Other patients may develop tumours in the face/nasal sinuses, testes, ovaries and skin.

In adults, the first symptoms of Burkitt's lymphoma include lymph node enlargement, swollen and painful abdomen, itching, fever and asthenia. The lymphoma frequently produces abdominal enlargement due to hepatosplenomegaly. Burkitt's lymphoma is 1000 times more common in AIDS patients than in the general population, and approximately 2% of AIDS patients develop Burkitt's lymphoma, with the majority having advanced (stage IV) disease at the time of diagnosis.

The treatment of Burkitt's lymphoma is multimodal: surgery in selected cases and chemoradiotherapy. Bulky abdominal tumours and those causing symptoms/complications are removed surgically before systemic therapy is instituted. In endemic disease, cyclophosphamide is used (orally or intravenously). Sporadic disease in children is treated with a short course of high-dose combination chemotherapy using cyclophosphamide with methotrexate, vincristine, prednisone and doxorubicin. Radiotherapy to the CNS and intrathecal methotrexate are used as prophylaxis against the spread of the lymphoma to the CNS and spine.

Adults with sporadic Burkitt's lymphoma are treated with a combination of radiotherapy and chemotherapy. High-dose chemotherapy with CODOX-M/IVAC, (cyclophosphamide, vincristine, doxorubicin, methotrexate, ifosfamide, etoposide and cytarabine) is commonly used. However, adults with AIDS because of their poor general state are usually given low-dose chemotherapy. Newer methods of treatment include bone marrow or stem cell transplantation and monoclonal antibodies, e.g. rituximab. Early results with rituximab combined with standard chemotherapy have shown improved remission rates and survival.

The prognosis in children is generally good. Children with African Burkitt's usually obtain a good response with cyclophosphamide. In the USA, 80% of children treated for early-stage disease obtain a good response and remain free from relapse for several years after treatment. Therapy with the CODOX-M/IVAC regimen has been reported to achieve cure rates of up to 90% in both children and adults. In patients with AIDS, the factors which influence outcome include the CD4 lymphocyte count; the presence of opportunistic infections, bone marrow involvement, spread beyond the lymph nodes, age and the patient's performance status. The prognosis is bad in patients with opportunistic infections, CD4 count <200, age above 35 years and low general health/performance status. The average survival of HIV-positive patients with Burkitt's lymphoma is 6 months.

Enteropathy-associated T-cell lymphoma

This T-cell tumour is aetiologically related to coeliac disease. However, it can arise in the absence of this condition. Enteropathy-associated T-cell lymphoma (EATL) accounts for 10–25% of all primary NHLs of the small bowel. The lesion is often multifocal and can form ulcers, strictures, plaques, nodules or diffuse thickening. In general the prognosis is poor and the disease tends to become disseminated at an early stage. EATL is a T-cell lymphoma of the intraepithelial T lymphocytes, composed of large lymphoid cells and often associated with necrosis and an inflammatory background, including large numbers of histiocytes and eosinophils, hence the former name of malignant histicyosis of the small intestine. The adjacent small intestinal mucosa shows villous atrophy, crypt hyperplasia, increased lamina propria lymphocytes and plasma cells. In 10–20% of cases, the lymphoma is composed of monomorphic medium-sized cells with no inflammatory background and rare necrosis (type II EATL).

EATL is encountered with greater frequency in those areas with a high prevalence of coeliac disease (northern Europe). It has been estimated that 2–3% of patients suffering from coeliac disease will develop an intestinal lymphoma, and in the majority this has the T-immunophenotype. Coeliac disease patients have a standardized incidence ratio of 5.81 for all NHLs and 40.51 for small bowel lymphomas. The interval between diagnosis of coeliac disease and development of EATL varies considerably.

Another condition associated with EATL is ulcerative jejunitis. Small bowel NHL T-cell lymphoma is also the most frequent extranodal site of NHL developing in solid-organ transplanted recipients, especially patients with renal graft transplants.

EATL usually develops in the jejunum or ileum as one or more ulcerating mucosal lesions that invade the wall of the intestine and frequently cause perforation. The neoplastic cells are medium–large with round or indented nuclei, prominent nucleoli with a rim of pale-staining cytoplasm. Less frequently, they are pleomorphic, mimicking anaplastic large cell lymphoma. An inflammatory background is often present, consisting of histiocytes and eosinophils. The intestinal mucosa adjacent to the neoplasm frequently shows enteropathy with villous atrophy, crypt hyperplasia, increased lamina propria lymphocytes and plasma cells and intraepithelial lymphocytosis. In type II EATL, the neoplastic cells are medium-sized with darkly stained nuclei and a moderate rim of pale cytoplasm. However, this type is not accompanied by an inflammatory background and necrosis is less evident than in classical EATL.

EATL classically presents in adults, usually with a history of coeliac disease. The presentation is with abdominal pain, often associated with jejunal perforation, weight loss, diarrhoea or bowel obstruction. Thus many cases are diagnosed at laparotomy. EATL is an aggressive lymphoma that is usually fatal and its treatment is not standardized. The role of surgery is limited to debulking or resection of masses with high risk of obstruction or perforation. Radiation therapy is indicated in some patients presenting with bulky disease, rectal lymphoma or after incomplete resection. Combined treatment with primary debulking resection and systemic anthracycline-containing chemotherapy, which may or may not be followed by radiation therapy, is used in fit patients. However, relapses after chemotherapy are common (80% of patients). Additionally, many patients are unable to complete chemotherapy and do not receive radiotherapy because of rapid progression of disease, poor nutritional and performance status and local/systemic complications. Some studies have suggested a better prognosis in patients after macroscopically complete resection and the use of chemotherapy. Others have used high-dose chemotherapy supported by autologous stem cell transplantation with encouraging results, including response rates in 50% of patients.

Alemtuzumab (humanized anti-CD52 monoclonal antibody) has also been used in patients in combination with gemcitabine or CHOP chemotherapy, and initial results are promising, although further phase II studies are needed.

Primary gastrointestinal follicular lymphoma

Follicular lymphoma is the second most common subtype of NHL and accounts for 20–25% of cases in the USA and Europe. The clinical course of the disease is typically indolent, although many patients relapse after treatment. The advent of anti-CD20 monoclonal antibodies (rituximab) has profoundly changed the therapeutic management of the disease.

Gastrointestinal follicular lymphoma (GI-FL) arises from antigen-responsive -cells predominantly of the duodenum or the small intestine. The disease may be unifocal or multifocal. As with other non-Hodgkin's follicular lymphoma, it has a low tendency to disseminate outside the gastrointestinal tract. GI-FLs resemble nodal FLs with respect to morphology and expression of typical markers such as CD10, CD38 and BCL-6. The tumour cells of GI-FL express high levels of the antiapoptosis protein BCL-2 and carry mutated immunoglogulin heavy-chain genes. In contrast to nodal FLs, the GI-FLs express the $\alpha4\beta7$ integrin, a mucosa-homing receptor also expressed by normal intestinal B- and T-lymphocytes and by low-grade MALT lymphomas.

GI-FL occurs most frequently in the duodenum. The Follicular Lymphoma International Prognostic Index (FLIPI) identifies patient subgroups with predictable outcome. FLIPI is based on five simple independent risk factors: haemoglobin <12 g/dL, serum LDH higher than upper normal value, Ann Arbor stage III–IV, number of nodal sites >4 and age >60 years. The prognosis of follicular lymphoma has improved in recent years with marked increase in the 5-year overall survival (from 64% to 95%). This improvement has been predominantly observed in patients with advanced (stage IV) disease and in younger patients. It is the result of the introduction of monoclonal antibody therapy. Prior to this, patients with stage III–IV disease were treated with systemic chemotherapy including various combinations of anthracycline with alkylating agents and interferon administration (either during chemotherapy or for maintenance). The advances in the last 10 years include (1) use of the monoclonal antibody rituximab alone as first-line therapy either as a short course or with maintenance; (2) rituximab as first-line therapy in combination with chemotherapy; (3) front-line therapy with radioimmunoconjugates, alone or after chemotherapy.

The reported results of front-line therapy with rituximab have shown a response rate of 75% to a standard weekly four-dose programme, with 50% of patients obtaining a complete response. However, in the absence of further treatment, the median time to disease progression is limited to a maximum of 24 months. Improved outcome is obtained with repeated rituximab courses consisting of 4 weekly infusions every 6 months for 2 years. This increases the median progression-free survival (PFS) to 34 months. A randomized study has shown a significantly improved PFS time in the maintenance arm (31 vs 7 months), with these patients being more likely to achieve a lasting. Several randomized studies on the use of conventional chemotherapy such as CVP (cyclophosphamide, vincristine, prednisone) with or without rituximab have confirmed improvement in response rates, PFS and overall survival favouring the rituximab-containing arm. In another trial (ECOG 4496), patients who did not progress after six to eight courses of the CVP regimen were randomly allocated to no further treatment vs consolidation with four cycles of 4 weekly rituximab infusions administered every 6 months for 2 years. This study demonstrated a significant improvement of 3 year PFS in the rituximab consolidation arm. Altogether, these studies demonstrate that a first-line treatment with rituximab with or after chemotherapy improves the outcome of these patients. The use of radioimmunoconjugates in the first-line treatment of patients with follicular lymphoma, either as a single agent or as consolidation therapy, has been demonstrated to improve patient outcome. Thus front-line therapy with ^{131}I-tositumomab achieves a very high response rate (95%), with 75% of patients achieving a complete response, a 5-year PFS of 59% and limited toxicity.

Inflammatory conditions of the small bowel

Crohn's disease

Crohn's disease is an idiopathic chronic inflammatory condition which can affect any part of the gastrointestinal tract and may also be associated with systemic manifestations. The disease is localized in the ileocolic region in 60% of patients, to the small bowel alone in 20% and to the colon alone in a further 20%. Perianal disease is common and may accompany more proximal disease. Colorectal and perianal disease are dealt with in chapter 30. Cases of Crohn's disease of the mouth, oesophagus and stomach are extremely rare. The disease is most common in North America and northern Europe, and although the prevalence is increasing in southern Europe it is relatively uncommon in other areas of the world. In the Far East it is almost never encountered.

Pathology

Irrespective of the site of involvement, Crohn's disease is a segmental condition with areas of involvement that are sharply demarcated from the contiguous normal bowel, at least to naked eye appearances. Particularly in small bowel disease, there may be several diseased segments with normal intervening bowel (skip lesions) but the number of such lesions is highly variable.

Macroscopic appearance

In early stages, the disease appears as mucosal inflammation with small aphthoid ulcers. In more advanced disease, the serosal surface of the affected bowel is granular and inflamed with a tendency for it to be encroached by mesenteric fat, so that the intestine may at times be buried within a swollen oedematous and foreshortened mesentery. On palpation, the involved areas feel heavy, thickened and firm as a result of the transmural inflammation that is usually associated with narrowing of the bowel lumen. Close inspection of the opened bowel reveals separation of the usual anatomical layers by fibrosis, which is particularly marked in the submucosal and subserosal layers (Figure 29.18). The mucosal oedema accounts for the characteristic cobblestone appearance of the mucosa (Figure 29.19). This oedema is followed by sloughing and linear ulceration of the mucosa, particularly at the mesenteric attachments (Figure 29.20). Pseudopolyps and mucosal bridges may form and the ulcers, which are typically deep and fissuring, penetrate into the muscle layers, and account for the tendency to localized perforation, adhesions and fistula formation. Regional lymphadenopathy is invariably present and usually the result of reactive hyperplasia.

Fistula formation is an important feature of Crohn's disease and accounts for substantial morbidity, long periods of debility and a 5–10% mortality following surgical treatment. The fistulous tracts may be simple or complex and often incorporate

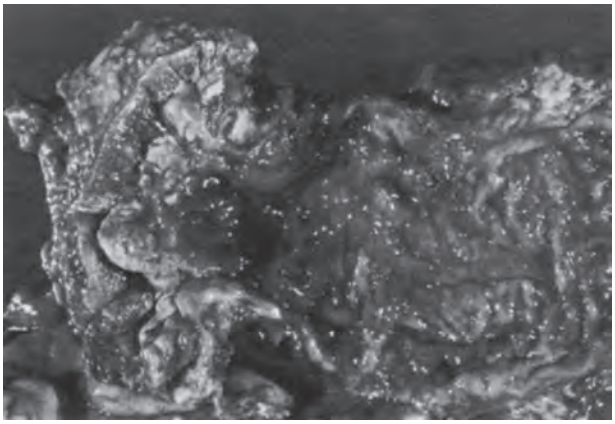

Figure 29.18 Crohn's disease of the ileocolic region. The affected bowel has been cut longitudinally to demonstrate the transmural fibrosis which is especially marked in the subserous and submucosal layers.

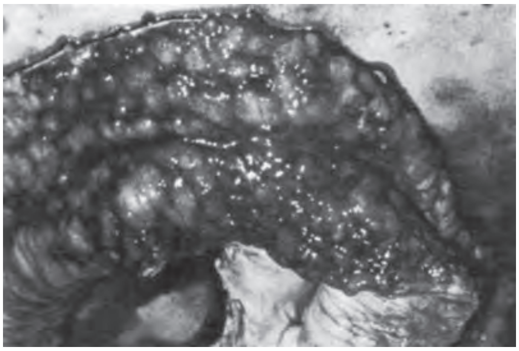

Figure 29.19 Diffuse mucosal/submucosal oedema resulting in the characteristic cobblestone appearance of the mucosa of Crohn's disease.

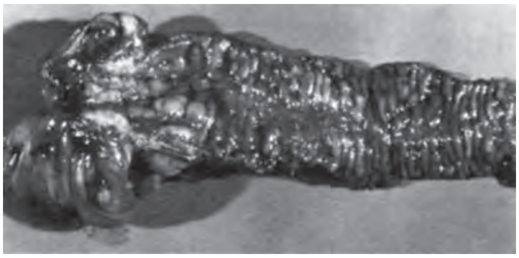

Figure 29.20 Extensive ulceration with stricture formation in Crohn's disease of the distal ileum. The longitudinal ulceration is more prominent along the mesenteric attachment.

intervening or associated abscesses. The important varieties of fistula encountered in Crohn's disease are listed below.

- *Enterocutaneous*: some 20–30% of these may heal with drainage of the associated abscess and parenteral nutrition.
- *Perianal fistulas*: these may be associated with severe anorectal disease but not in all cases.
- *Ileocolonic fistulas*: these can lead to diarrhoea and severe bacterial overgrowth of the small intestine leading to malabsorption and malnutrition.
- *Enterovesical fistulas*: these may involve the ileum or the colon or both and usually develop in patients with longstanding disease. Enterovesical fistulas are less common than the other varieties and have a reported incidence of about 5%. They usually follow a benign course and present with dysuria, pneumaturia and recurrent pyelonephritis. They do not respond to conservative measures and require surgical intervention.

Microscopic appearances

The histological features of Crohn's disease are characterized by a transmural inflammation consisting of chronic inflammatory cell infiltrates, including eosinophils, crypt abscess formation, oedema, non-caseating epitheloid cell granulomas containing giant cells (Langerhans cells), dilatation and sclerosis of the intestinal lymphatics and lymphoid aggregates with or without germinal centres. These are all found in the various layers of the bowel wall associated with epithelial regenerative changes and angiitis. These granulomas, which resemble those found in sarcoidosis, are found in the bowel wall in 50–60% of cases and to a lesser extent (25%) in the regional lymph nodes. The epithelial regenerative changes include the development of pseudopyloric gland metaplasia. The non-caseating granulomas are the most important criterion for the histological diagnosis of Crohn's disease and in their absence it can be very difficult to make the distinction between Crohn's disease and ulcerative colitis when the disease affects the large intestine.

Aetiology

The aetiology of Crohn's disease remains obscure. However, the various hypotheses may be considered under the following headings: genetic factors, environmental factors, infective agents, immunological factors and vasculitis.

Genetic factors

There is a familial tendency to develop Crohn's disease and about 10% of patients have an affected first-degree relative. There is no consistent HLA association but patients with ankylosing spondylitis are at greater risk of Crohn's disease than the general population and this association appears to be linked with tissue type HLA B27. A susceptibility locus for Crohn's disease has been mapped on chromosome 16. The gene (*NOD29*) determines the body response to some bacterial proteins. Mutations of *NOD29* are present in individuals who develop Crohn's disease. Other genes, e.g. the autophagy related 16-like 1 gene (*ATG 16L1*) and *IRGM*, which cause defective macrophage function, have also been implicated. The intestines of patients with Crohn's disease harbour higher titres of certain strains of *Escherichia coli* which have also been implicated in the pathogenesis through defective clearance of these bacteria consequent on impaired intestinal mucosal macrophage activity.

Environmental factors

The possible role of diet has been widely investigated and is thought to account for the large geographical differences in the prevalence of Crohn's disease. There are no reliable data linking fibre consumption with Crohn's disease, but several studies show a high intake of refined carbohydrates by Crohn's patients compared with appropriate controls. Smoking is probably an important factor, with smokers having a greater risk than those who have never smoked. This is in contrast with ulcerative colitis, where smoking appears to be protective. There also appears to be an increased risk of Crohn's disease in women taking oral contraceptives.

Infective agents

There is little epidemiological support for the suggestion that Crohn's disease may be infective. Investigations for evidence of clustering in time or space have not been able to demonstrate any evidence of person-to-person transmission, and studies on healthcare professionals dealing with Crohn's patients do not indicate an increased risk. However, some work suggests that low-virulence bacterial yeast or *Chlamydia* organisms may be responsible and two particular types of bacteria have been extensively investigated.

The variant or L-form bacteria have deficient cell walls and can develop from several bacterial species after exposure to antibiotics. The cell wall protein deficiency is accompanied by an alteration in virulence, antigenicity and pathogenicity. However, these variant bacteria, which can pass through filters holding back normal bacteria, can in time and under certain conditions revert back to their original form. *Pseudomonas maltophilia* is a variant bacterial species that has been isolated from intestinal Crohn's disease.

Mycobacterium paratuberculosis is an atypical mycobacterium which has been isolated from patients with Crohn's disease and on inoculation has been shown to produce granulomas in animals. In addition, patients with Crohn's disease have been shown to have IgG antibodies against this organism. However, the antibody levels do not bear any relation to disease activity and their level is not altered by resection of diseased bowel. Recent studies of DNA hybridization have revealed mycobacterial genomes in the tissues of patients with Crohn's disease, providing further indirect evidence of the possible role of the organism in Crohn's disease.

Immunological factors

Although humoral immune responses appear to be normal in patients with Crohn's disease, cell-mediated immunity is not. Some patients have impaired skin hypersensitivity, a reduction in circulating T-lymphocytes and a poor response to non-specific mitogens. It is quite possible however that these defects result from the disease itself or associated malnutrition rather than being aetiological factors. An abnormal permeability of the mucosal epithelium is well documented and it is possible that this could lead to exposure of the subepithelial immune cells to foreign protein, thus setting up an immune reaction in the wall of the intestine. This theory is supported by the favourable response of Crohn's disease to an elemental diet. Abnormal activation of the GUT immune system in Crohn's may be responsible for the chronic inflammation and ulceration. The susceptibility to abnormal activation of the immune system is genetically inherited.

Vasculitis

This hypothesis has been suggested following the demonstration of intestinal vascular pathology (vasculitis) in the evolution of Crohn's disease. In essence it implicates multifocal gastrointestinal microinfarction as the cause of Crohn's disease. This theory however remains unsubstantiated.

Clinical features

The peak incidence of Crohn's disease is in the third decade and it occurs with the same frequency in females as in males. It may however also affect children and elderly people. In the latter age group, it is frequently colonic and accompanied by diverticular disease. The clinical manifestations of Crohn's disease are extremely varied and depend on the location and the extent of disease. There are also a number of complications which can determine the presenting features. The 'syndromes' by which Crohn's disease can present include the pseudoappendicitis syndrome, small bowel obstruction, abscess formation, fistula formation, diarrhoea, growth retardation and portal venous gas.

Pseudo appendicitis syndrome

Some patients with Crohn's disease of the terminal ileum develop acute abdominal pain, the severity and location of which all simulate acute appendicitis. Some 14% of children and young adults with Crohn's disease present in this manner. This clinical presentation is of particular importance as acute terminal ileitis often due to *Yersinia* infection is often encountered in many instances and has a very different natural history from that of Crohn's disease. Approximately one in eight cases of acute terminal ileitis are due to Crohn's disease. Accordingly, in the emergency situation the treatment should be conservative. The appendix should be removed if the caecum appears normal and swabs taken from the luminal contents for bacteriological culture. Appendicectomy will prevent further diagnostic dilemmas at a later stage. However, if the caecum and the base of the appendix appear to be affected by disease, appendicectomy should not be carried out as this may lead to fistula formation.

Small bowel obstruction

Crohn's disease of the small bowel gives rise to abdominal pain because of acute or subacute small bowel obstruction (Figure 29.21). Complete small bowel obstruction is relatively rare. Patients with intermittent self-limiting obstructive episodes invariably have gross bacterial overgrowth which may give rise to further malabsorption, hypoproteinaemia and, malnutrition.

Abscess formation

This is a common presentation. Abscesses may result either from bowel perforation which may occur at the site of a deep fissuring ulcer or proximal to a stricture. It can also arise in a mass of inflamed regional lymph nodes without perforation of the bowel. Apart from the local signs and symptoms, abscess formation leads to malaise, weight loss, fever and anorexia. The commonest site of abscess formation is in the right iliac fossa. This may track into the pelvis along the psoas muscle underneath the inguinal ligament and present as a tender groin mass (psoas abscess). Free perforation of Crohn's disease into the peritoneal cavity with widespread peritonitis is extremely unusual.

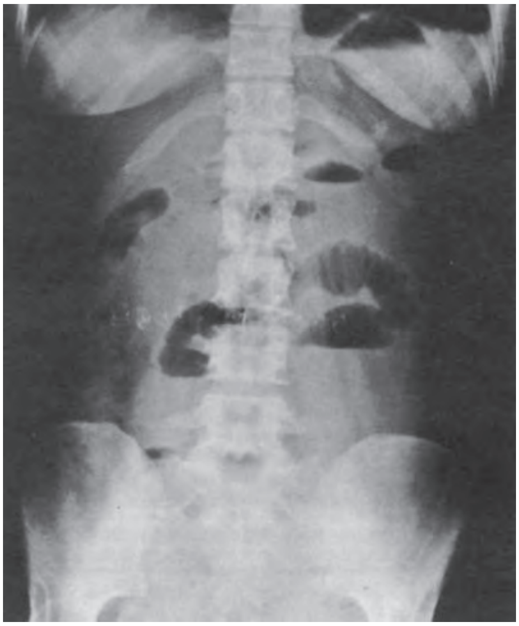

Figure 29.21 Plain erect abdominal film showing air/fluid levels in a stepladder pattern due to mechanical small bowel obstruction. The patient had had a previous right hemicolectomy for Crohn's disease. Such an obstructive picture may be due to adhesions or recurrence which is most commonly situated at the level of the previous resection.

Fistula formation

The most common type is perianal, which usually occurs in association with perianal abscesses and sinuses (Figure 29.22). These perianal complications are a significant feature of Crohn's disease and may be present months or years before intestinal symptoms are noticed. Enterocutaneous fistulas usually become evident following drainage of abdominal abscesses and can be classified as high or low output in terms of the amount of intestinal contents which discharge everyday. Spontaneous closure with parenteral nutrition is more likely in the low-output variety. Enterocolic fistulas are associated with bacterial overgrowth, malabsorption and frequently diarrhoea (Figure 29.23). Enterovesical fistulas due to Crohn's disease do not usually cause severe systemic disturbance and present with urinary symptoms (see above).

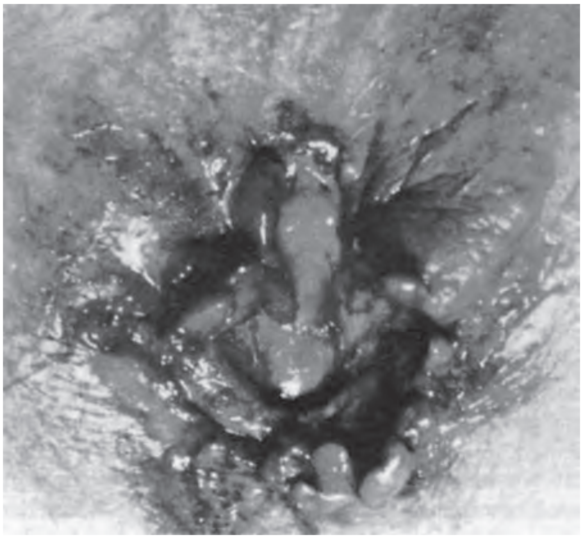

Figure 29.22 Extensive anal and perianal disease in a patient with Crohn's colitis. The patient had a high fistula *in ano*.

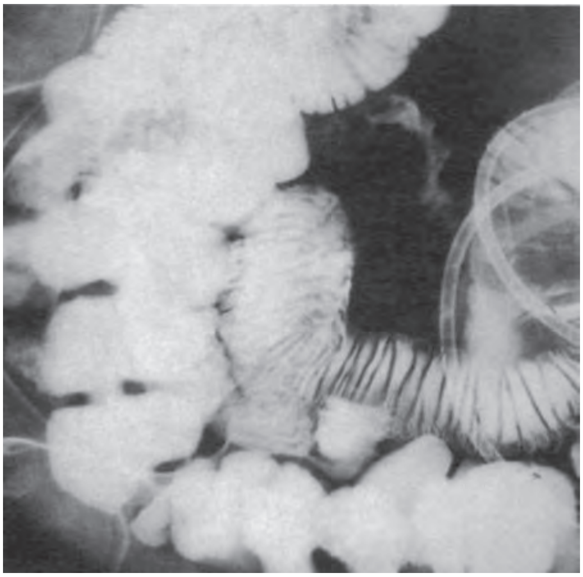

Figure 29.23 Barium study demonstrating a fistula between the small bowel and the colon in a patient with Crohn's disease.

Diarrhoea

Diarrhoea occurs in about 70–80% of patients with Crohn's disease. It is particularly common in patients with terminal ileal involvement, and this is thought to be related to the failure of the terminal ileum to reabsorb bile salts. Diarrhoea associated with colonic disease is accompanied by the passage of mucus and blood from the rectum and is very similar to the symptomatology of ulcerative colitis. Such diarrhoea is often accompanied by a protein-losing enteropathy and steatorrhoea due to bacterial overgrowth or bile salt malabsorption.

Growth retardation

This occurs in approximately 20% of all children with Crohn's disease. Failure to thrive in children with Crohn's disease has four basic components: impaired linear growth, weight loss or failure to gain weight, delayed sexual maturation and closure of epiphyses and normal endocrinological parameters. Thus thyroid function in these children is consistently normal and so is growth hormone secretion when several provocative tests are employed. The major factor in growth retardation is malnutrition which is due to failure to eat because of high-grade partial intermittent small bowel obstruction, protein and blood loss from the ulcerated inflamed areas of the small bowel and malabsorption due to bacterial overgrowth. When assessing the potential growth of these children it is crucial to evaluate their bone age and to note the stature of their parents. In this way it is possible to predict which children would be capable of responding to therapeutic intervention (including parenteral nutrition). Following an appropriate bowel resection, growth resumes the normal pattern but compensatory growth does not occur. It is therefore essential to treat these children while their bones are still capable of growth. Fortunately, in many of these teenagers closure of the epiphyses is delayed because of the associated malnutrition.

Portal venous gas

This potentially fatal complication has been described in patients with Crohn's disease. The patient develops severe toxicity with high fever and rigors and severe diarrhoea. The gas in the portal vein is best detected by abdominal CT scanning and indicates portal bacteraemia. All patients who develop this complication have active disease. Treatment of this complication is not standardized as it is a very rare complication, but broad-spectrum antibiotics active against both Gram-negative aerobes and anaerobes, steroids and intravenous fluids are generally recommended in the first instance with laparotomy and resection of the diseased segment of bowel if there is no improvement.

Diagnosis

Suspicion of Crohn's disease is based on symptoms and signs (fever, abdominal pain and tenderness, diarrhoea with or without bleeding, and anal disease). Initial laboratory screening shows elevated white blood cell counts and ESR and hypochromic microcytic anaemia. Firm diagnosis then rests on correlation of the clinical manifestations with endoscopic, radiological and histological findings.

Certain laboratory tests are important to establish the nutritional state of the patients and as an index of disease activity. A full blood count, ESR, serum electrolytes, serum proteins and in particular serum albumin are important. Decreased serum albumin, hypochromic microcytic anaemia and low serum iron may be found in as many as 50% of untreated patients. Occasionally, a megaloblastic anaemia may be observed as a result of folic acid deficiency or impaired vitamin B_{12} absorption. Hypocalcaemia, hypomagnesaemia, low serum level of zinc and low serum vitamin A may also be present reflecting impaired absorption or decreased ingestion. Frank malabsorption with steatorrhoea may be present in patients with extensive small bowel disease or bacterial overgrowth. In these patients the Schilling test or the SeHCAT test may prove useful in defining the presence of malabsorption of vitamin B_{12} and bile salts respectively. Bacterial overgrowth is documented by the hydrogen breath tests and the oral ^{14}C-glycocholate test. Important indices of disease activity are ESR, serum α-1-glycoprotein level, C reactive protein and OKT9 lymphocyte positivity.

Radiological appearances

Barium contrast studies (follow-through or small bowel enema) usually identify the disease and define its distribution. Other investigations which must be performed in suspect cases include proctoscopy and colonoscopy. Biopsy material is essential for establishing the diagnosis. CT and MRI enterography provide excellent evaluation of the severity and extent of the Crohn's disease.

In small bowel disease affected segments are most commonly demonstrated by means of a small bowel enema or follow-through. Narrowing of the lumen, nodularity of the mucosal pattern, thickening of the ileocaecal valve, mucosal irregularity and deep ulcerations perpendicular to the intestinal lumen (rose thorn ulceration) and fistula formation are all characteristic's features of Crohn's disease. Long narrow strictures result in the well-known string sign of Kantor (Figure 29.24). Skip lesions are characteristic with normal bowel in between the strictured or diseased areas. Fistulas and sinuses may be evaluated by injection of contrast medium following insertion of catheters of the appropriate size to ensure a close fit. MRI provides detailed information of the pathological anatomy of the fistula and is especially useful in complex types with multiple and branched tracts (Figure 29.25).

More recently, CE has been used for the diagnosis of Crohn's disease and is reported to provide superior results to contrast studies and CT although it carries a risk of capsule impaction in patients with strictures. Thus it is contraindicated in patients with colicky abdominal pain and other obstructive symptoms.

Complications

Although intestinal obstruction abscess formation and fistula formation are technically complications of Crohn's disease, they are so common that they are usually regarded as integral clinical features of the disease. Crohn's disease may however be accompanied by systemic manifestations of inflammatory bowel disease. These include sclerosing cholangitis, skin problems such as pyoderma gangrenosum and erythema nodosum, arthritis and uveitis.

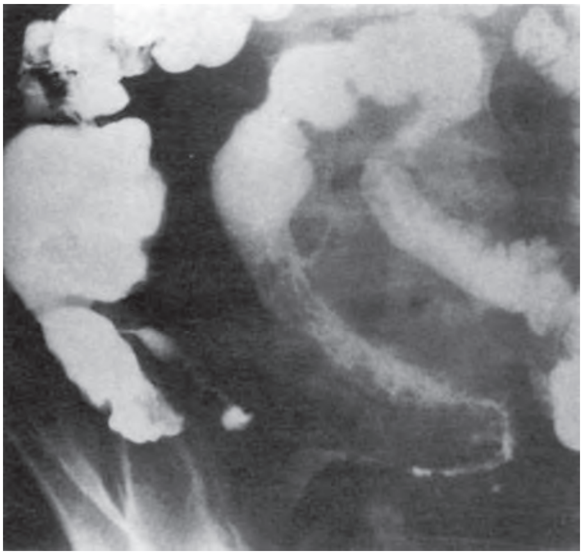

Figure 29.24 Small bowel enema showing several features of Crohn's disease of the distal ileum: stenosis (Kantor's string sign), cobblestoning of the mucosa, deep glandular ulcer (pseudodiverticulum), deep penetrating fissure ulcers, wide separation of the intestinal loops due to thickening of the bowel walls and thickening of the ileocaecal valve due to lymphatic blockage and oedema. The patient presented with intermittent cramp-like abdominal pains after meals.

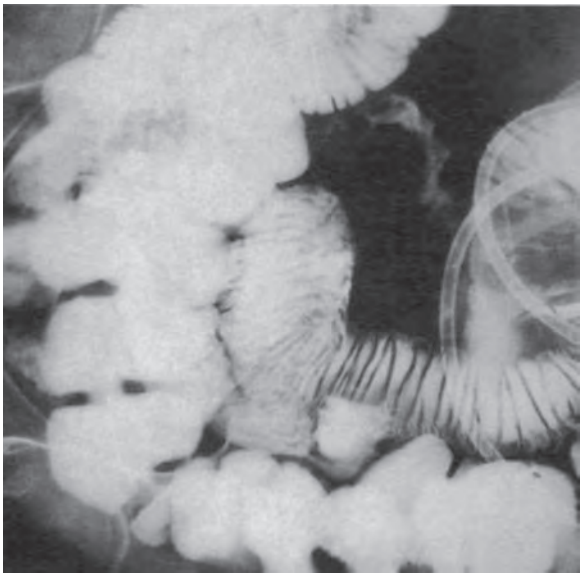

Figure 29.25 Small bowel study demonstrating a fistula between the small bowel and the colon in a patient with Crohn's disease.

In addition to enterovesical fistulas the urological complications of Crohn's disease include an obstructive uropathy and an increased incidence of renal calculi. The obstructive uropathy is caused by retroperitonitis and fibrosis leading to obstruction of the ureter (usually on the right) and is more frequent than is clinically appreciated (Figure 29.26). Patients with obstructive uropathy are usually totally asymptomatic although occasionally pyuria, bacteriuria and pain in the renal

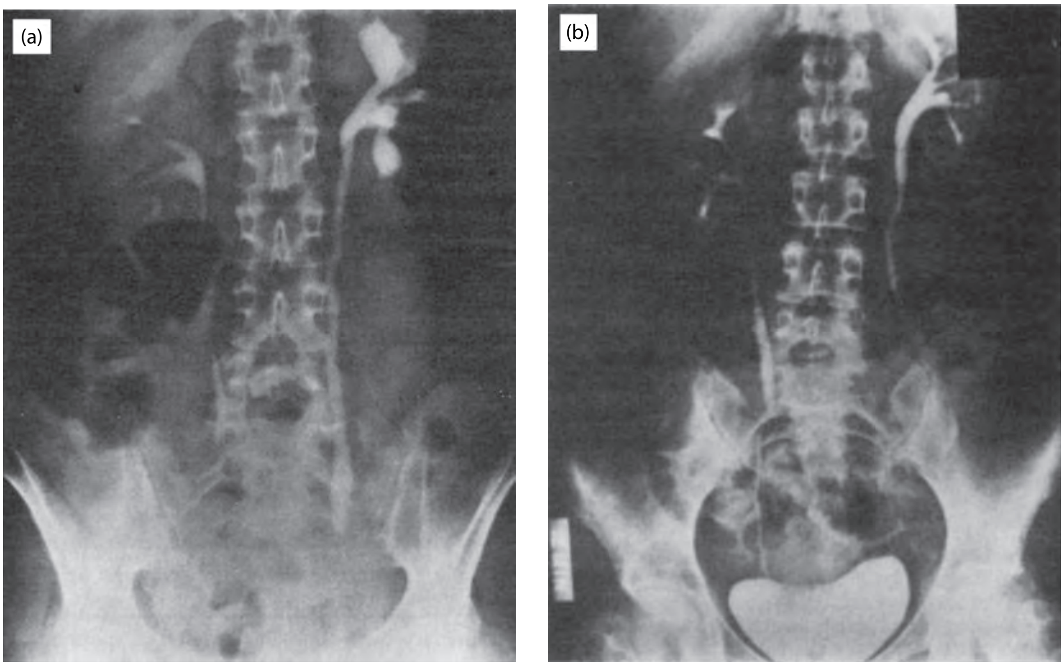

Figure 29.26 (a) Intravenous urogram demonstrating an obstructive uropathy on the left side. The patient had Crohn's disease of the ileum with fistula formation involving the sigmoid colon and resulting severe inflammation of the retroperitoneal tissue on the left side; (b) the same patient 1 month following bowel resection and ureterolysis – there is complete resolution of the left hydronephrosis and hydroureter.

angles are observed. If untreated, obstructive uropathy can lead to severe hydronephrosis, recurrent pyonephrosis and loss of functional renal tissue. Imaging of the kidneys is therefore an important part of the work-up of patients with Crohn's disease using either intravenous urography or cross-sectional imaging (ultrasound or CT scanning). Renal calculi have been reported in 10% of patients with Crohn's disease and in most of these patients the duration of disease has been longstanding. Calcium oxalate or phosphate stones account for 72% of cases and uric acid stones for 18%. Some 10% of the renal calculi cannot be classified. Only 36% of patients with renal stones have a predisposing urinary tract abnormality such as sponge kidney, obstructive uropathy or a metabolic disorder such as hypercalcaemia. Increased absorption of oxalate and increased cell turnover in the gut and concentrated urine appear to be important factors in the formation of renal calculi in patients with Crohn's disease. The prevalence of renal stones in children with Crohn's disease is said to be as high as 25%.

There is also an increased incidence of gall stone formation in patients with severe ileal Crohn's disease or following ileal resections. This is attributable to malabsorption of bile salts with interruption of the enterohepatic circulation and a consequent reduction of the bile salt pool. In addition, there is now a well-established association between Crohn's disease and small bowel adenocarcinoma. These tumours occur at a younger age and are located predominantly in the distal ileum. Cases of small bowel lymphoma and carcinoid tumours have also been reported in patients with Crohn's disease.

Treatment

There is no curative medical or surgical treatment for Crohn's disease. The aim of medical therapy is to (1) induce remission, (2) prevent relapse, (3) minimize side effects of medication and (4) improve the quality of life. Medical treatment can be further subdivided into dietary modifications, parenteral nutrition and drug treatment.

Selection of treatment regimen has to be individualized and depends on disease severity, disease location and presence of complications. There are two contrasting approaches to the medical therapy in Crohn's disease: the traditional step-up approach and the more recent top-down management. In the former regimen, initial treatment is with the least toxic agents for mild disease, with more aggressive therapy being reserved for severe disease, or for patients who fail to respond to the initial medication. The more recent top-down approach involves early aggressive therapy from the start aimed to decrease exposure to anti-inflammatory agents and use of agents which enhance mucosal healing, thereby preventing future complications. This approach has been gaining favour in recent years.

Dietary modification

In patients with extensive disease the first priority is to correct deficiencies including vitamins (especially A), magnesium and zinc. Iron-deficiency anaemia is treated with oral supplements preferably in the glutamate form. There are various reports of benefit derived from low-fibre, low-refined-sugar diets and from the use of exclusion diets. In the latter, patients are started on distilled water and then items of food introduced and maintained or withdrawn according to whether or not they aggravate the condition. It appears that the most common dietary components which require exclusion are dairy products and wheat. There is some evidence for the benefit of an elemental diet (e.g. Vivonex, Flexical or Ensure) in suppressing mucosal inflammation. The effect of elemental diets is thought to result from a reduction of the foreign protein load presented to the inflamed mucosa. The problems with long-term use of elemental diets include their expense and their unpalatability, which reduces compliance in the long term. Dietary supplements of calcium, folate and vitamin B_{12} are needed in patients with malabsorption. The use of antimotility agents (diphenoxylate and atropine, loperamide) and antispasmotics may relieve abdominal colicky attacks and diarrhoea.

Parenteral nutrition

This is of value in the following situations:

- intestinal failure with gross nutritional deficiencies and severe hypoalbuminaemia
- malnourished patients prior to surgery
- in obtaining remission in patients with severe active disease
- in patients with enterocutaneous fistulas.

Long-term home parenteral nutrition is reserved for patients with extensive small bowel disease or resection and intestinal failure. The patients are taught to self-administer the parenteral feeds and to look after their central lines and it offers a reasonable quality of life. Some patients require only intermittent supplemental intravenous feeding and manage reasonably well with modified or elemental diets in the intervening periods. Home parenteral nutrition is supervised by the medical and nursing staff of specialized nutrition units.

Intravenous feeding is necessary on a short-term basis for patients with complications requiring elective surgical intervention but who are malnourished. Improvement to the nutritional status and elevation of the serum albumin above 3 g/L is essential for the safe healing of intestinal anastomoses. Some 30% of enterocutaneous fistulas due to Crohn's disease may heal spontaneously with the use of parenteral nutrition, but persistence of a fistula beyond 6 weeks indicates failure of this approach and the need for surgical intervention.

Some advocate cessation of oral feeding and total parenteral nutrition for several weeks to achieve remission in active Crohn's disease. Although the immediate results of this approach are good, relapse is almost invariable within 3 months of resumption of oral intake.

Drug therapy

There is a wide range of drugs which are used in the management of Crohn's disease, indicating that no one drug is universally effective and that the treatment has to be individualized in accordance with the severity of the disease of the patient. All the medications fall in to five classes: (1) anti-inflammatory agents, (2) predominantly immunosuppressive drugs, (3) anti-tumour necrosis factor (TNF)-α agents, (4) anti-α-4 integrin and (5) methotrexate, which is both an immune-depressant and an anti-inflammatory drug.

Anti-inflammatory drugs

These agents decrease intestinal inflammation and include (1) 5-aminosalicylic acid (5-ASA) compounds such as sulfasalazine and mesalamine, which act by direct contact (as topical agents) with the inflamed mucosa, (2) corticosteroids as systemic agents to decrease inflammatory response by the body and (3) antibiotics. Systemic steroids incur significant side effects with long-term use. However, budesonide (semisynthetic topical corticosteroid), which acts on direct contact with the inflamed mucosa, has fewer side effects. The antibiotics used include metronidazole (Flagyl) and ciprofloxacin. Both decrease the inflammation in Crohn's disease although exact their mechanism remains unknown.

5-Aminosalicylic acid drugs

Oral 5-ASA is effective in both Crohn's disease and ulcerativcolitis. Mesalamine enema contains 5-ASA and is used in rectal disease, but, for proximal and ileal disease, 5-ASA must be taken orally. When administered orally, most of the 5-ASA is absorbed in the stomach and the upper small intestine, and very little 5-ASA reaches the ileum and colon. Hence, modified 5-ASA, which is not absorbed by the stomach and the upper small bowel, is used, e.g. sulfasalazine (5-ASA linked to sulfapyridine). Sulfasalazine is effective in inducing remissions in patients with mild to moderate disease. It is also used to prolong remissions. When sulfasalazine reaches the ileum and the colon, intestinal bacteria release the active 5-ASA. Most of the side effects of sulfasalazine are due to the sulfapyridine moiety and include nausea, heartburn, headache, anaemia, skin rashes, and, rarely, hepatitis and nephropathy. In males, sulfasalazine can reduce the sperm count. The newer 5-ASA compounds, e.g. mesalamine, do not have the sulfapyridine moiety and thus have fewer side effects than sulfasalazine, and, for this reason, are nowadays used more frequently. Asacol is an oral preparation consisting of 5-ASA coated with acrylic resin which prevents absorption of the 5-ASA in the stomach and upper small intestine. The resin dissolves as it reaches the terminal ileum and colon, releasing the active 5-ASA. Asacol is used for inducing remission primarily in patients with mild to moderate ulcerative colitis but several reports have also documented its efficacy in Crohn's ileitis and ileocolitis, and in maintaining remission from this disease. Pentasa is a capsule containing only 5-ASA. The 5-ASA is released slowly as the capsule travels down the small intestine and is active in terminal ileal Crohn's disease and the colon. It is currently the most commonly used 5-ASA compound for mild to moderate small bowel Crohn's disease. Pentasa is also used to maintain remission and reduce recurrence in patients after surgical excision of Crohn's disease. Olsalazine is a special formulation of bound 5-ASA molecules which prevents its absorption in the stomach and upper small intestine. The intestinal bacteria then break the chemical bonds, releasing the active 5-ASA molecules in the terminal ileum and colon where the bacterial counts are high. Olsalazine is effective for maintenance of remission in ulcerative colitis but it induces diarrhoea and, for this reason, it is not used often nowadays. Balsalazide capsules contain 5-ASA linked to an inert molecule which prevents absorption of the 5-ASA until it reaches the terminal ileum and colon, where bacterial activity splits the compound, releasing the 5-ASA. 5-ASA enemas and suppositories are used in the treatment of ulcerative colitis involving only the distal colon. They are also effective in treating rectal Crohn's disease. 5-ASA in suppositories is used for the same indications and may be useful in maintaining remission in patients with distal ulcerative colitis.

Corticosteroids

Steroids are used in patients with moderate to severe Crohn's disease and ulcerative colitis. Administered intravenously and orally, they remain the most appropriate treatment for severe disease or cases not responding to 5-ASA therapy. In some patients, they may also be necessary to maintain remission. Corticosteroids are indicated in Crohn's disease, ulcerative colitis and Crohn's colitis. In critically ill patients, corticosteroids are administered by intravenous injection. In patients with proctitis, hydrocortisone enemas are use to control the rectal inflammation. Although corticosteroids exert a much faster action than 5-ASA in inducing a remission, they are much less useful than 5-ASA in preventing relapse of the disease in both Crohn's disease and ulcerative colitis. The problem with corticosteroid therapy relates to their adverse side effects which are frequent and often severe especially during prolonged high-dose therapy. Thus, whenever possible, short courses of corticosteroids are used. The important side effects of corticosteroid therapy include fluid retention with the development of a moon face, acne, hirsutism, diabetes, hypertension, cataracts, glaucoma, immunosuppression with increased risk of infection, muscle weakness, depression, insomnia, personality change, osteoporosis and aseptic necrosis of the hip and knee joints (in 3–4% of patients). Another potentially fatal complication of long-term steroid therapy is adrenal atrophy such that acute adrenal insufficiency occurs on withdrawal of treatment. Thus corticosteroids should always be reduced gradually to enable recovery of adrenal function. Even after safe withdrawal of corticosteroids, the ability of the adrenal glands to produce cortisol can remain depressed for several months up to 2 years. This hypocorticalism may not be able to produce increased amounts of cortisol in conditions of stress (accidents, surgery, and infections) and thus results in adrenal insufficiency.

The majority of patients with Crohn's disease respond to an oral dose of 40–60 mg of prednisone with an improvement in symptoms within a few weeks. Once symptomatic improvement has been achieved, the dose is reduced by 5–10 mg per week to 20 mg daily. The dose is thereafter reduced at a slower rate until cessation of treatment. Aside from obviating the risks of acute adrenal insufficiency, this gradual reduction also reduces the risk of relapse of the inflammation. In patients who achieve remission with corticosteroids, 5-ASA compounds often are continued alone to maintain remission.

In patients whose symptoms return during gradual withdrawal of prednisone, the dose is increased slightly until control of symptoms is achieved, when reduction of corticosteroids can be resumed gradually. Unfortunately, many patients become corticosteroid dependent. In such patients and in patients who are unresponsive to corticosteroids and other anti-inflammatory medications, immunomodulator medications or surgery should be considered.

Budesonide (semisynthetic steroid) is a potent anti-inflammatory drug with a topical action on the inflamed tissues in Crohn's disease and has no systemic effect. On absorption, it is rapidly metabolized in the liver (first pass) to inactive compounds. Budesonide capsules contain granules (Entocort) that enable slow release of the drug into the ileum and the colon. In a double-blind study involving patients with Crohn's ileitis and/or Crohn's disease of the right colon, budesonide was found to be more effective than Pentasa in inducing remissions. Other studies have shown however that although it is no more effective than corticosteroids in inducing remission in Crohn's disease, it has fewer side effects. Trials have indicated that budesonide 5 mg per day as a single morning dose is as effective as 40 mg of prednisolone daily, and because it causes fewer side effects it is commonly used in the management of patients with active Crohn's disease. Budesonide also suppresses the adrenal glands but to a lesser extent than systemic corticosteroids. Budesonide is not effective in maintaining remission in patients with Crohn's disease.

Antibiotics

These include metronidazole (Flagyl) and ciprofloxacin. Metronidazole has some activity in the treatment of Crohn's colitis and is particularly useful in patients with perianal fistulas. Both antibiotics can induce symptomatic remission in active Crohn's disease. However, chronic use of metronidazole in doses higher than 1 gram daily can lead to a peripheral neuropathy. Patients on metronidazole must avoid alcohol because this combination causes severe nausea, vomiting, cramps, flushing and headache. Ciprofloxacin is used in the treatment of Crohn's disease either alone or in combination with metronidazole.

Symptomatic treatment for diarrhoea includes the administration of loperamide or codeine phosphate and non-addictive analgesics for the abdominal pain. Cholestyramine may improve steatorrhoea in patients with extensive ileal disease or resection.

Immunosuppressive drugs

These are used to abrogate the abnormally activated immune response in severe Crohn's disease. Their risk is an increased susceptibility to infections. The drugs in this category used in Crohn's disease are: 6-mercaptopurine (6-MP), azathioprine, methotrexate and anti-TNF-α antibodies, e.g. infliximab, adalimumab, certolizumab and natalizumab.

Azathioprine (Imuran) and 6-MP have been used for many years in the treatment of patients with moderate to severe Crohn's disease and ulcerative colitis. Azathioprine is chemically related to 6-MP and is converted into 6-MP in the body. They are indicated in:

- severe Crohn's disease and ulcerative colitis not responding to steroids
- in patients who develop serious corticosteroid-related side effects
- in patients who develop corticosteroid dependency (patients become unable to discontinue steroid therapy without relapse of their disease)
- to maintain remission.

In patients with severe Crohn's disease characterized with frequent relapses, despite 5-ASA, low-dose azathioprine and 6-MP are used to maintain remission. Perianal fistulas usually respond to treatment with metronidazole, but this treatment may fail in some patients who may then respond to azathioprine and 6-MP. Aside from increased susceptibility to infections, the other side effects of azathioprine and 6-MP include hepatitis, pancreatitis and bone marrow depression.

Thiopurine methyltransferase (TPMT) levels are important in the safe use of azathioprine and 6-MP. Azathioprine is converted into 6-MP in the body and 6-MP then is partially inactivated by TPMT before elimination. The activity of TPMT enzyme is however genetically determined, and approximately 10% of individuals have reduced or absent TPMT activity. These patients thus accumulate 6-MP with consequent risk of bone marrow toxicity manifested by leucopenia and reduced resistance to life-threatening infections. TPMT levels must be checked in each patient prior to initiation of treatment with azathioprine or 6-MP. Patients with low or absent TPMT activity are best treated with other drugs or prescribed substantially low doses of 6-MP or azathioprine and checked frequently for marrow depression. Additionally allopurinol must not be prescribed together with azathioprine or 6-MP as it reduces TPMT activity.

The combination of azathioprine and 6-MP in low doses (as distinct from the larger doses used in preventing rejection of transplanted organs) is effective in patients with moderate to severe Crohn's disease and ulcerative colitis with documented efficacy in 70% of patients. Azathioprine and 6-MP are indicated:

- in severe Crohn's disease and ulcerative colitis not responding to corticosteroids
- in patients who develop adverse effects on corticosteroid therapy
- in patients who develop corticosteroid dependency
- to maintain remission after surgical excision for complicated disease as an alternative to 5-ASA
- in patients with failed healing of perianal fistulas after treatment with metronidazole.

Anti-TNF-α agents

Infliximab (Remicade) is a humanized mouse antibody that binds to TNF-α, one of the cytokines produced by immune cells during activation of the immune system. TNF-α then stimulates other immune cells to initiate the cytokine cascade involved in the inflammatory response. Crohn's disease is characterized by excess continued production of TNF-α. Hence, infliximab, which binds and blocks the action of TNF-α, abrogates the inflammation. Infliximab is used with success (65% response) in the treatment of moderate to severe Crohn's disease patients who respond inadequately to corticosteroids, azathioprine or 6-MP. Improvement is observed within days in some patients and within 2 weeks in the majority after commencement of the drug, which is administered by intravenous infusion. Infliximab is also effective in the healing of resistant perianal fistulas. Repeated infusions of infliximab every 8 weeks are used to maintain remission in many patients over a 1–2 year period. Response to infliximab after repeated infusions however declines and the drug may cease to be effective due to the development of antibodies to the infliximab.

Currently, infliximab is used for fast symptomatic control of active and severe disease when it is stopped and followed by maintenance treatment with azathioprine, 6-MP or 5-ASA compounds. There is some evidence that azathioprine or 6-MP may also help in preventing or delaying the development of antibodies against infliximab. Although generally well tolerated, adverse effects may occur during infliximab infusions. These include chest pain, shortness of breath, nausea and headaches. There is also an increased risk of infection including pneumonia and tuberculosis (TB). Hepatosplenic T-cell lymphoma has been reported in patients with Crohn's disease on azathioprine therapy alone or in combination with infliximab. Additionally, patients also may develop a delayed allergic reaction 7–10 days after receiving the infliximab with flu-like symptoms (fever, joint pain and swelling) and a worsening of Crohn's disease activity index.

The current recommended treatment with infliximab consists of a three-dose cycle at time zero, 2 weeks and 4 weeks to induce a remission with maintenance infusions every other month or 6-MP or 5-ASA compound. Infliximab is contraindicated in patients with existing infections, e.g. pneumonia, urinary tract infections, or abscess formation. In view of the reported cases of TB, it is now recommended that patients should be tuberculin tested before receiving infliximab.

Adalimumab (Humira) is another anti-TNF-α agent with similar action to infliximab but is administered subcutaneously. Several clinical trials have confirmed its efficacy in reducing signs and symptoms of Crohn's disease. It is also helpful in treating arthritis and arthralgias in patients with moderate to severe active Crohn's disease. In other respects, therapy with adalimumab provides equivalent results to infliximab in inducing and maintaining remission in patients suffering from Crohn's disease. Like infliximab, it is also effective in healing perianal fistulas. It is also effective in patients who do not respond or who are intolerant to infliximab. In adult patients adalimumab is administered subcutaneously every 2 weeks.

The most common side effects of adalimumab are skin reactions at sites of injection with swelling, itching and erythema. Other common side effects include upper respiratory infections, sinusitis and nausea. As with infliximab, adalimumab increases the risk of infection and the same precautions are needed including tuberculin testing prior to commencing treatment. It is also contraindicated in established infections. There have been reports of deteriorating cardiac function and heart failure in patients on infliximab or adalimumab.

Certolizumab pegol (Cimzia) is a pegylated humanized antibody fragment also directed against TNF-α with similar actions to infliximab and adalimumab. Although unlike these monoclonal antibodies certolizumab is an incomplete antibody and, therefore, does not induce *in vitro* complement activation. It is used in patients with moderate to severe Crohn's disease who do not respond adequately to standard medical therapy. Certolizumab is effective in inducing and maintaining clinical remissions for over 3.5 years. The standard dose of certolizumab is 400 mg subcutaneously at week 0, week 2 and week 4 to induce remission. Maintenance dosing is with 400 mg subcutaneously every 4 weeks.

Certolizumab is well tolerated. The most common side effects necessitating cessation of treatment include abdominal pain and diarrhoea. Intestinal obstruction has been reported but is rare. Hypersensitivity reactions have also been reported including angioedema, allergic dermatitis, shortness of breath, hot flushes, hypotension, malaise and syncope.

Anti-α-4 integrin

Natalizumab (Tysabri) is a humanized monoclonal antibody to alpha-4 integrin, also effective in patients with moderate to severe Crohn's disease unresponsive to aminosalicylates, antibiotics, corticosteroids, immunomodulators, or TNF-α inhibitors. It targets the cellular adhesion molecule α-4-integrin, which is expressed on leucocytes involved in the pathogenesis of Crohn's disease. The recommended dose is 300 mg by intravenous infusion over 1 hour every 4 weeks. It must not be used in conjunction with immunosuppressants or TNF-α inhibitors. The most common adverse effects are headache, fatigue, upper respiratory infections and nausea. The most serious adverse events are hypersensitivity, immunosuppression/infections and progressive multifocal leucoencephalopathy (PML), which is caused by reactivation of a latent human JV polyoma virus and is usually fatal.

Methotrexate

This acts as both an immunodepressant and anti-inflammatory agent and has been in established use for several years in treating patients with moderate to severe Crohn's disease who are either resistant or intolerant to azathioprine and 6-MP. It is administered either orally or by weekly subcutaneous or intramuscular injection. When used over long periods (years) it may cause hepatic cirrhosis. This risk is higher in patients who drink alcohol in excess and in severely obese patients. Other side effects of methotrexate include low leucopenia and pulmonary fibrosis. Because of potential damage to the foetus, methotrexate is contraindicated in pregnancy.

The Second European evidence-based consensus recommends management protocols which depend on disease severity (Box 29.1).

BOX 29.1 Second European consensus on evidence-based management of Crohn's disease

Mild to moderate active disease

- Oral mesalamine 3-4 g daily or sulfasalazine for ileocolonic or colonic disease as 3–6 g daily in divided doses
- Budesonide (9 mg/day) for disease confined to the ileum and/or right colon
- Proton pump inhibitors in patients with upper gastrointestinal Crohn's disease

Moderate to severe disease

- Prednisone 40–60 mg/day until resolution of symptoms
- Appropriate antibiotic therapy for infection or abscess
- Azathioprine and 6-MP for maintaining a steroid-induced remission
- Methotrexate 25 mg/week for steroid-dependent and steroid-refractory Crohn's disease
- Infliximab, adalimumab, and certolizumab pegol for moderate to severe disease in patients who do responded to steroid or other immunosuppressive drugs
- Natalizumab for patients with moderate to severe disease who do not obtain an adequate response or are unable to tolerate conventional Crohn disease therapy and anti-TNF antibody therapy

Perianal or fistulizing disease

- Surgical drainage of abscesses
- Treatment with antibiotics (metronidazole), immunosuppressives, or infliximab

Surgical treatment

Owing to the chronic relapsing nature of Crohn's disease surgical treatment can never be regarded as curative but it has an extremely important role to play; and all patients with Crohn's disease should have the benefit of a combined medical and surgical approach. Surgical intervention is indicated for the complications of the disease and for active disease which has not responded to medical therapy. However, there is considerable morbidity associated with the surgical treatment and about half of the deaths of patients with Crohn's disease are associated with operative intervention. It has to be appreciated, however, that patients coming to surgery for Crohn's disease often have serious complications of the disease.

Surgical treatment is indicated in Crohn's disease only for:

- excision of a diseased segment causing small bowel obstruction
- treatment of perforation
- drainage of intra-abdominal or perirectal abscesses
- treatment of severe perianal and anal fistulas unresponsive to medical treatment
- resection of symptomatic internal fistulas
- complications of medical management in particular in patients with major side effects of steroid therapy
- growth retardation in children
- development of obstructive uropathy
- massive haemorrhage (rare).

The resection must aim to conserve as much as is possible of the small bowel and for this reason must be strictly limited to the diseased segment(s). In many patients, however, Crohn's disease eventually recurs, affecting previously healthy bowel. As recurrence is common after resection (50% within 4 years of surgery), treatment with drugs such as mesalamine, Pentasa or 6-MP is recommended to reduce the risk of relapse. Infliximab has also been shown to be effective in reducing postoperative recurrence after ileocaecal resection, although relapse may occur when this treatment is stopped.

Other factors which influence the decision to operate and the type of operative procedure include the anatomical site of the disease, the surgeon's preference and expertise and whether the operation is being performed as an emergency or as an elective procedure. The extra gastrointestinal manifestations of Crohn's disease are rarely, if ever, an indication for operative intervention, and certainly in small bowel disease resection does not appear to have a major effect in this respect.

When making an abdominal incision it should be planned with attention paid to previous incisions and the siting of a stoma. Laparoscopic assisted surgery is appropriate for patients with isolated terminal ileal or ileocolic disease where a limited right hemicolectomy is required and several such reported series have documented the benefit of the laparoscopic approach in these patients. Many patients, however, still require open surgery. At laparotomy, an initial exploration is carried out to determine the extent and severity of the disease and to establish the state of the liver and the presence and otherwise of gall stones. Adhesions which are often present are taken down and the anatomy and the length of the small intestine ascertained.

The emphasis of modern surgical treatment for small bowel disease is on the maximal preservation of intestine with resections being strictly limited to the diseased segment causing the symptom or complication. Bypass should only be carried out when there is no other alternative, as blind loops encourage bacterial overgrowth, increased incidence of abscess and fistula formation and risk of developing carcinoma. In deciding the extent of small bowel resection a balance must be struck between removing all grossly diseased bowel and retaining sufficient for adequate absorption and nutritional support. Macroscopic assessment of the disease is used to determine the extent of the resection. The important macroscopic features in this respect include thickening of the bowel wall and mesentery, hyperaemia and oedema, fat encroachment of the bowel and the presence of ulcers at the resection line. It is now established that areas of minimal disease may be safely left as there is no evidence that microscopic disease at the resection margin reduces the recurrence rate. Skip lesions in the vicinity of the main disease process may be safely excised *en bloc* but those at a distance should be resected separately if considered significant.

Conservative (non-resectional) surgery is particularly indicated in patients with multiple previous resections and in those with multiple strictures. In order to determine whether or not a small area of disease is causing a significant stricture, it is useful to manipulate the balloon of a Fogarty catheter along the lumen of the bowel introduced via an enterotomy. This will give some indication as to the size of the lumen at the strictured site. If the stricture admits the passage of an 18–20 mm inflated balloon, intervention is probably not necessary.

Stricturoplasty is now widely used for the treatment of strictures. The type of procedure used depends on the length of the stricture, a Heineke–Mikulicz stricturoplasty being ideal for short stenotic areas (Figure 29.27) and the Finney equivalent for long strictures (Figure 29.28). The decision between a stricturoplasty and a resection for a long stenotic segment is dependent on surgical experience and expertise and it has to be remembered that stricturoplasty is associated with postoperative morbidity including a leak rate of around about 10%. Although there are no prospective randomized trials the immediate outcome of stricturoplasty appears to be similar to that encountered after resection for small bowel Crohn's disease and there is no evidence that there is a significant increased risk of recurrence after stricturoplasty.

Compared to resection, stricturoplasty is not appropriate in the presence of sepsis (abscess) and fistula, both of which are best treated by resection. Adhesions and fistulas between diseased segments of bowel and adjacent hollow viscus are dealt with by careful separation of the diseased segment from the adjacent structure with debridement and primary closure of the latter. External fistulas are managed by similar excision with debridement and closure of the abdominal wall but not of the skin and the subcutaneous tissues. Secondary wound closure is performed several days later. If there is a mass involving several loops of bowel the surgeon must carefully identify and dissect healthy from diseased bowel. Provided that the length involved is not great, a resection en mass may be performed. After the small bowel resections have been completed the length of the residual small intestine must be measured along the anti-mesenteric border and recorded.

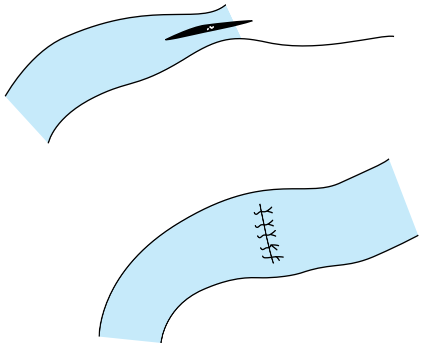

Figure 29.27 Diagrammatic representation of the technique of Heineke-Mikulicz stricturoplasty. This operation is suitable for short strictures in the absence of active inflammation. An operative biopsy with frozen section histology is advisable to exclude carcinoma.

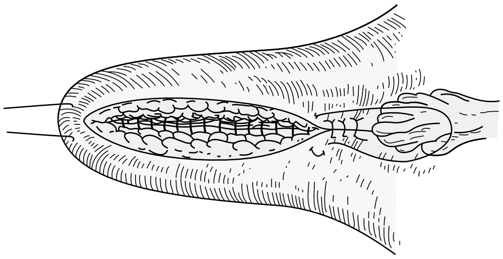

Figure 29.28 Diagrammatic representation of Finney-type stricturoplasty for long stenosed segments of Crohn's disease.

Free perforation into the peritoneal cavity is rare in Crohn's disease and the commonest site is the ileum. Resection of the diseased segment with peritoneal lavage and debridement is the treatment of choice. Primary anastomosis or exteriorization is performed depending on the duration and the severity of the peritoneal inflammation. Simple drainage of an abscess invariably results in a fistula. As described above, some 30% of enterocutaneous fistulas may heal with total parenteral nutrition but persistence of the fistula beyond 6 weeks is an indication for surgical intervention with excision of the diseased segment of bowel. Enterocolic and enterovesical fistulas never heal by conservative management and always require surgical intervention. Perforation of the diseased bowel into the retroperitoneal tissues causes intense fibrosis and retroperitoneal inflammation resulting in an obstructive neuropathy. Although the obstructed ureter may be asymptomatic the resulting renal impairment may be progressive and permanent. Hence, obstructive uropathy is an absolute indication for surgery and is best relieved by appropriate bowel resection and ureterolysis.

Operations for Crohn's disease are followed by a high incidence (10–15%) of postoperative complications such as anastomotic leakage, fistula formation, intra-abdominal abscess and haemorrhage. The overall reported mortality rate ranges from 2% to 8%. A high mortality is associated with emergency operations (up to 30%). Late postoperative complications include short bowel syndrome, urinary lithiasis, cholelithiasis, gastric hypersecretion and peptic ulcer disease.

One of the unresolved problems is the high incidence of recurrence following resection. Accumulative recurrence after resection of small intestinal Crohn's disease is 30% at 5 years, 50% at 10 years, and 60% at 15 years. Young patients and those with ileocolic disease have the highest and earliest recurrence and the worst ultimate prognosis. The prognosis of patients with Crohn's colitis undergoing proctocolectomy is better in this respect as the development of ileal disease occurs in 10% and 20% of these patients at 5 and 10 years respectively. After abdominal colectomy and ileorectal anastomosis the reported recurrence rate averages 50% at 5 years. The majority of recurrences occur at or near the anastomosis and in patients with ileorectal anastomosis. The recurrent disease often involves the ileum and further resection does not necessarily require proctectomy and ileostomy.

In assessing the widely divergent reported figures for recurrence rates after surgical intervention for Crohn's disease two points must be stressed: (1) the recurrence rate rises gradually with the duration of follow-up and (2) it is essential to differentiate patients with true recurrent Crohn's disease from those requiring reoperations for other complications including ileostomy revisions.

Many patients with Crohn's disease undergo multiple resections and a significant percentage of these develop the short gut syndrome. At present the majority of these patients are managed by home parenteral nutrition which may be complicated by catheter sepsis, venous thrombosis and parenchymal liver disease. Recently the development of more effective immunosuppressive drugs (cyclosporin especially) and the discovery of the protective effect of a concurrent liver transplant (especially on graft-vs-host disease) has led to the successful use of combined hepatic and small bowel transplantation. The early results have been encouraging but it has yet to become a routine procedure. One of the major concerns is the possibility of recurrence of Crohn's disease in the transplanted bowel but there are very little data to support this at present.

Polyarteritis

Pathology

This condition is characterized by a systemic necrotizing vasculitis with fibrinoid necrosis and an inflammatory cell infiltrate affecting the blood vessels (arteries and veins) of several organs including the small intestine. The weakened vessels lead to aneurysm formation, which may rupture and bleed or thrombose causing multiple organ infarcts. There are several categories of polyarteritis but the two which affect the gut most frequently are polyarteritis nodosa (PAN) and the *Churg–Strauss syndrome* (CSS) also known as allergic granulomatous angiitis because of the eosinophilic infiltration and granuloma formation in the connective tissue in addition to the vasculitis.

Aetiology

The pathogenesis of PAN is unknown but, in some cases, PAN is associated with viral infections, especially hepatitis B virus (HBV) (10–15%). Evidence for immune complex-induced disease is thus confined to HBV-related PAN and the role of immune complexes in non-HBV-related PAN remains unclear. Impaired function of endothelial cells may be part of idiopathic PAN or a consequence of it.

CSS is a granulomatous small-vessel vasculitis of unknown cause. There is no firm evidence for the role of immune complexes or cell-mediated mechanisms in CSS, although autoimmunity is involved as indicated with the presence of hypergammaglobulinaemia, increased levels of IgE and rheumatoid factor. A CSS-like syndrome may develop in patients with asthma who are steroid-dependent on treatment with leukotriene receptor antagonists on reduction of the oral steroid dose. The steroid withdrawal is thought to unmask the syndrome although patients have been documented who developed vasculitis when a leukotriene receptor antagonist was substituted for inhaled steroids in the absence of oral steroid withdrawal.

Clinical features

The American College of Rheumatology (ACR) recommends the presence of at least three out of the following criteria for establishing a clinical diagnosis of PAN. Additionally the diagnosis should be confirmed by biopsy:

- livido reticularis (mottled purplish discoloration of the skin of the torso and extremities)
- testicular pain
- muscle pain, weakness and tenderness
- neuropathy (single or multiple)
- hypertension (systolic >90 mmHg)
- impaired renal function (blood urea nitrogen >40 mg/dL or creatinine >1.5 mg/dL)
- positive HBV test for surface antigen or antibody
- angiograpy showing vascular damage (aneurysms or stenosis)
- biopsy showing arteritis (necessary for confirmation).

The ACR also recommends the following criteria for the diagnosis of CSS. The presence of four or more criteria yields a sensitivity of 85% and a specificity of 99.7%:

- asthma (wheezing, expiratory rhonchi)
- eosinophilia of more than 10% in peripheral blood
- paranasal sinusitis
- pulmonary infiltrates (may be transient)
- histological proof of vasculitis with extravascular eosinophils
- mononeuritis multiplex or polyneuropathy.

In addition to systemic manifestations (fever, weight loss, malaise and hypertension) the symptoms emanating from involvement of the small intestine include nausea, vomiting, diarrhoea and steatorrhoea.

Complications

PAN and CSS can lead to life-threatening complications such as intestinal infarction, perforation and massive gastrointestinal haemorrhage.

Treatment

Medical treatment with corticosteroids and either cyclophosphamide or azathioprine is the mainstay of therapy. Surgery is only undertaken for the major complications which entails resection of the affected segment of small bowel. Particularly in cases of infarction the ends should be exteriorized rather than attempting a primary anastomosis with subsequent restoration of continuity once bowel viability is assured.

Plasma exchange is indicated in HBV-related PAN, where it is the most effective treatment after an initial short-tem course of prednisone and is administered in conjunction with antiviral medications, e.g. vidarabine and interferon-α. Plasma exchange is not effective and is therefore not indicated in PAN not associated with HBV infection and in CSS. Prednisone in combination with cyclophosphamide is the current recommended first-line treatment in these cases despite infectious side effects, which can be reduced by dose adjustment to the neutrophil and lymphocyte counts.

Eosinophilic gastroenteritis

Eosinophilic gastroenteritis (EGE) is an uncommon gastrointestinal disease affecting both children and adults which is characterized by (1) the presence of gastrointestinal symptoms which may be chronic or acute, (2) eosinophilic infiltration in one or more areas of the gastrointestinal tract, defined as 20 or more eosinophils per high-power field in the absence of an identified cause for the eosinophilia and without involvement of extra gastrointestinal tissues.

Aetiology and pathology

The aetiology and underlying molecular mechanisms responsible for EGE are not known although recent studies implicate the role of esosinophils, T helper 2 and chemokines (eotaxin) in the pathogenesis. Eosinophils function as antigen-presenting cells and express major histocompatibility complex class II molecules. They are known to mediate proinflammatory effects, including the upregulation of adhesion molecules, modulating cell trafficking and inducing cell activation by releasing various cytokines and transforming growth factor-α/β, chemokines (RANTES and eotaxin) and lipid mediators (platelet-activating factor and leukotriene C4). Additionally, eosinophils can induce tissue damage by releasing toxic granule proteins, e.g. eosinophilic cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin.

The disease may manifest as eosinophilic gastritis or enteritis. Atopy is present in a subset of patients, as demonstrated by raised total IgE on food-specific IgE radioallergosorbent assay test (RAST) or skin tests. Macroscopically the wall of the affected segment is thickened and there are small mucosal ulcers.

Clinical features

The clinical manifestations vary with the site of involvement in the gastrointestinal tract and the extent of histological involvement of the gut wall: mucosal, muscularis or serosal disease. Patients present usually in the third to fifth decades of life, but the disease can affect any age group, including infants. The disease most often involves the stomach and the small bowel. The mucosal form of EGE is characterized by vomiting, dyspepsia, abdominal pain, diarrhoea, faecal blood loss, iron-deficiency anaemia, malabsorption, protein-losing enteropathy and failure to thrive in children. The muscularis form may present with gastrointestinal obstructive symptoms mimicking pyloric stenosis or intestinal obstruction. The less common serosal form presents with significant bloating, ascites and very high peripheral eosinophilia.

Diagnosis

Diagnosis is based on history, clinical picture, elevated IgE, endoscopy and biopsy and elevated peripheral eosinophil counts. Some cases presenting with pyloric or intestinal obstruction are first diagnosed at laparotomy. The raised blood eosinophil count should alert the clinician to the possibility of EGE.

Treatment

The treatment of EGE is unsatisfactory. When a short segment of diseased small bowel is encountered at laparotomy for intestinal obstruction, the segment is usually resected and the diagnosis established by the subsequent histology. However, surgery is not advisable if the diagnosis is made preoperatively; treatment is medical with corticosteroid therapy and surgery is reserved for patients in whom the obstructive symptoms persist.

In addition to oral steroids or cromolyn, patients with mucosal disease may also benefit from diet elimination therapy, particularly those with a history of food intolerance or allergy.

Radiation enteropathy

Pathology

The immediate effect of radiation on the gastrointestinal tract is arrest of cell division in the intestinal crypts. This effect is largely restricted to cells in the G1 phase. With greater radiation exposure, oedema and ulceration of the mucosa ensue. As a result of the diminished cell turnover the mucosa becomes thinner with stunted villi. If there is extensive small intestinal involvement, malabsorption of varying degrees will occur.

The long-term effects are due to transmural fibrosis following the appearance of atypical fibroblasts in the submucosa and ischaemia from a proliferative endarteritis and vasculitis.

Obliteration of the intestinal lymphatics with lymphatic ectasia complicates the pathological picture. The oedema is most marked in the submucosal layer. The fibrosis which affects all the coats is progressive and accompanied by hyalinization. The muscle layers exhibit areas of myofibrillar degeneration with atrophy of the muscle fibres, patchy hyalinization and disturbed motility. The serosa becomes thickened, opaque and greyish white and dense adhesions develop between adjacent intestinal loops.

Incidence

Although the figure of 5% is often quoted for the incidence of intestinal radiation-induced bowel disease in patients who receive radiotherapy to the abdominal and pelvic regions, the individual estimates vary from 3% to 25%. There is however general agreement that the prevalence is probably underestimated due to lack of clinical recognition. The cumulative 10 year morbidity after abdominopelvic radiotherapy is estimated at 8%, with severe enteropathy accompanied by major complications (bleeding and obstruction, stenosis and fistula formation, malabsorption and perforation with peritonitis) in 3%. The most common situation is where the pelvis is irradiated, usually for rectal or gynaecological cancer. In the normal situation and particularly after rectal excision, loops of small bowel lie in the pelvis and are at great risk of irradiation.

Clinical features

Symptoms are encountered in the majority of patients during the first few weeks of radiotherapy. Anorexia, nausea and vomiting are CNS effects as these are often encountered in patients receiving radiotherapy in extra-abdominal regions. These early symptoms usually subside rapidly and do not necessarily indicate the development of late sequelae that characterize radiation-induced bowel disease.

The commonest symptoms referable to chronic bowel damage are vague abdominal discomfort, diarrhoea, mild rectal bleeding and the passage of mucus. The interval between the time of radiation and onset of symptoms varies considerably from 2 months to 2 years. Intestinal obstruction may be acute or subacute and recurrent. Occasionally, acute presentation with infarction may occur and this carries a high risk of perforation and mortality. Most of the serious late complications tend to occur within 2 years of the initial treatment but may become progressively worse with time.

Diagnosis

The investigative procedures used in the assessment of patients include contrast radiology of the small and large intestine and malabsorption studies. Sigmoidoscopy and colonoscopy may be appropriate in patients with large bowel disease.

Complications

As indicated under Clinical features, the main complications are intestinal obstruction and perforation secondary to infarction (Figure 29.29). Fistula formation can also occur.

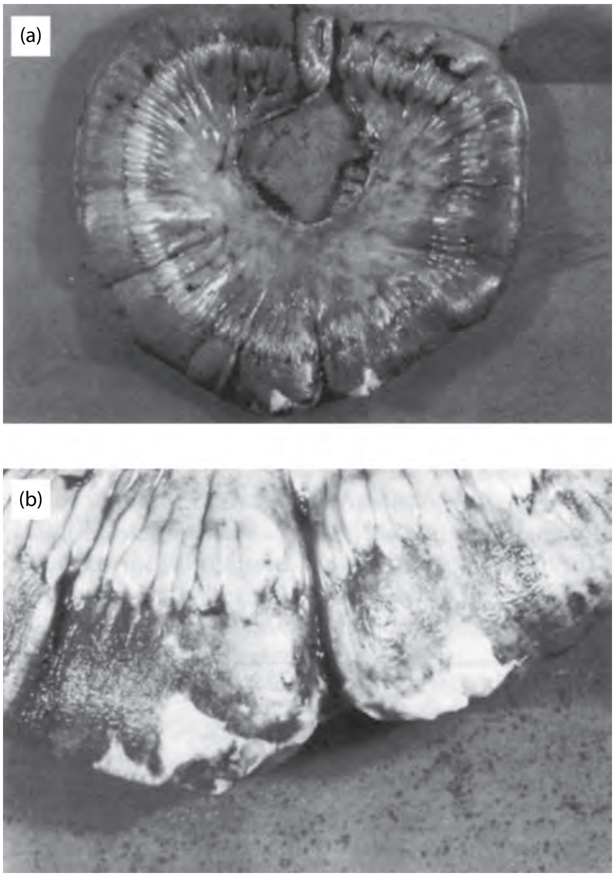

Figure 29.29 (a) Emergency resection of infarcted radiation enteropathy of the small bowel; (b) close-up of the perforation.

Treatment

Prophylaxis

This is of great practical importance and includes medical, radiotherapeutic and surgical measures.

The preventive medical measures designed to decrease the effects of radiation on the gastrointestinal tract include:

- maintenance of adequate hydration
- sulfasalazine, 500 mg orally twice daily, reduces the incidence and severity of radiation-induced enteropathy in patients receiving external beam radiotherapy
- amifostine (a prodrug which is converted to its intracellular metabolite, WR-1065), which acts as a radioprotectant. Oxidation of WR-1065 produces metabolites which act as scavengers of free radicals, thus minimizing DNA damage. Amifostine administered intravenously (340 mg/m^2) has been shown to decrease the incidence of radiation proctitis in patients receiving radiotherapy for rectal cancer
- sucralfate, orally and as enemas, is used as a mucosal protective agent in the prophylaxis against radiation enteropathy, with variable results
- glutamine, which is the preferred metabolic fuel for enterocytes, also has antioxidant function and is used both in the prophylaxis and in the treatment of established disease
- hyperbaric oxygen therapy is also used in the prophylaxis of radiation proctitis.

The various techniques used to minimize radiation-induced damage to the gut in patients requiring abdominopelvic external radiotherapy are:

- multidirectional, sharply collimated beams
- multiple-field, conformal therapy with prior three-dimensional planning
- computer-assisted dosimetry
- more stable intracavitary applicators
- extended intervals between fractionated doses and a lower dose per fraction.

Surgical measures are used in patients undergoing surgery who will require postoperative radiotherapy. They are based on the principle of reperitonealization and abdominopelvic partitioning and are aimed at excluding the mobile small bowel from the pelvic cavity where the small bowel loops become adherent to each other and to the pelvic wall. Both native tissue and prosthetic material are used to create a partition between the abdominal and pelvic cavities or to retain the small bowel within the abdominal cavity after surgery. In reperitonealization procedures, native tissue (peritoneum, omentum, urinary bladder, uterine broad ligaments) are used for the partitioning of the two pelvic cavities. In omental-based procedures, an omental flap based on the left gastroepiploic pedicle is used to retain the small bowel within the abdominal cavity. Prosthetic procedures include the use of absorbable mesh slings and less commonly temporary pelvic space-occupying devices such as inflatable balloons or silicone implants which have to be removed after the completion of radiotherapy.

Medical therapy of radiation enteropathy

A low-fat, low-residue, lactose-free diet (many patients become intolerant of lactose) is recommended, with octreotide being reserved for patients who do not obtain symptomatic relief. Nausea is treated with antiemetics. Other agents of marginal value include 5-ASA and sucralfate as a mucosal protective agent. Iron supplementation is administered in patients with low-grade bleeding leading to iron-deficiency anaemia. Topical steroids and sucralfate enemas are indicated for chronic radiation proctitis. The presence of significant malabsorption necessitates further measures, such as antibiotics for bacterial overgrowth and bile salt binding agents (cholestyramine) for ileal disease together with careful dietary management, the use of elemental diets and oral supplements. Glutamine-supplemented elemental diets are needed in patients with severe malabsorption. Some patients with extensive small bowel disease and severe malabsorption require parenteral nutrition intermittently or indefinitely.

Surgical treatment of radiation enteropathy

Whenever possible, management should be conservative as surgical treatment has a high morbidity and an average reported mortality of 25%. Emergency surgery is required for infarction with perforation or acute intestinal obstruction which does not resolve on conservative treatment. The radionecrotic bowel is ideally excised with primary anastomosis or exteriorization of the bowel ends in the presence of ischaemia and sepsis. Occasionally when the small bowel is firmly adherent within the pelvis, dissection of the affected segments may be hazardous and ileoileal or ileocolonic bypass may be more appropriate. Elective surgery may be undertaken for chronic severe symptoms due to stricture or internal fistula formation and the same considerations apply. In the performance of these operations only these adhesions which are in the operative field should be divided. Extensive adhesiolysis should be avoided as this is hazardous and can be complicated by perforation.

Infective conditions of the small bowel

Campylobacter gastroenteritis

Campylobacter species are among the most common pathogens in humans and are commensal in many animals (chickens, other birds, swine and cattle). The organisms constitute the most common cause of culture-proven bacterial gastroenteritis/colitis in both developed and developing countries and the incidence in the number of cases often exceeds those of salmonellosis and shigellosis. Thus these infections have become a major public health problem and, according to the WHO, *Campylobacter* genus is one of the most frequently isolated bacteria from stools of infants with diarrhoea in developing countries.

Clinical features

Whereas in developing countries *Campylobacter* gastroenteritis has no seasonal incidence, epidemics have been well documented during summer and autumn in developed countries. Although *Campylobacter* gastroenteritis/colitis is usually a mild self-limiting disorder with diarrhoea and colicky abdominal pain, it may rarely cause a severe infection associated with bacteraemia, abscess formation and other internal abdominal infections. When severe, the disease may also be associated with the development of the Guillain–Barré syndrome (acute inflammatory demyelinating polyneuropathy).

The diagnosis is made on stool culture but occasionally because of undiagnosed severe abdominal pain and tenderness a laparotomy may be performed usually with negative results. However, there are rare instances of *Campylobacter* appendicitis, cholecystitis and pancreatitis.

Treatment

Rehydration and correction of electrolyte abnormalities constitute the treatment. Debate exists on the need for antibiotic therapy. This is certainly not indicated in patients with mild disease and should only be considered for patients with severe symptoms, fever and bloody diarrhoea, and in immunosuppressed patients. *Campylobacter* species are often resistant to several antibiotics including penicillin, ampicillin and cephalosporins. Although most strains are susceptible to erythromycin, azithromycin, gentamicin and tetracycline, resistance may develop. When antibiotic therapy is indicated, erythromycin for 5–7 days is considered the appropriate treatment. Except in the patients with severe disease, there is considerable debate on the benefit of antibiotic therapy especially as a significant therapeutic effect is only observed when treatment is commenced early during the course of illness. There are very few randomized studies that compare antibiotics with placebo for the treatment of *Campylobacter* species-related diarrhoea. Some of these studies have concluded that antibiotics have no effect; but a meta-analysis showed a significant decrease in symptoms and bacterial shedding time together with a trend towards a beneficial effect when early antibiotic treatment was started.

Yersinia infections

These Gram-negative coccobacillary rods belong to the family Enterobacteriaceae. The organisms belong to the genus *Yersinia,* which includes 11 species, only three of which are pathogenic to humans: *Y. pestis* (bubonic plague), *Y. pseudotuberculosis* (mesenteric adenitis), and *Y. enterocolitica*. *Yersinia* species are Gram-negative, oxidase-negative, and non-lactose-fermenting bacilli.

The two species which cause gastrointestinal infections particularly of the terminal ileum, appendix, ascending colon and mesenteric lymph nodes are *Y. enterocolitica* and *Y. pseudotuberculosis*. The infection induces a granulomatous inflammatory picture with microscopic abscess formation which may simulate chronic inflammatory bowel disease. The ileum and ascending colon may become swollen, ulcerated and exhibit macroscopic appearances similar to Crohn's disease.

Pathology

Transmission is primarily via ingestion of contaminated foods, including pasteurized milk and dairy products as *Yersinia* can proliferate at refrigerated temperatures. There are 34 serotypes of O antigen of *Y. enterocolitica*, types 0:3 (sporadic cases); 0:5,27; 0:8 (foodborne outbreak); and 0:9 being the most common and virulent types. *Y. enterocolitica* grows in environments with a low pH 5–9, hence the increased incidence of the disease in patients who take antacids and acid suppression drugs. Also, the organisms require iron to multiply, and this accounts for the reported cases in patients with iron overload (haemochromatosis).

After ingestion the bacteria reach the terminal ileum which is the site of mucosal adherence and penetration. This is followed by bacterial proliferation in the Peyer's patches followed by the development of non-specific ileocolitis with an inflammatory infiltrate in the lamina propria (usually limited to the right colon). The bacteria may then spread to the mesenteric lymph nodes, which may then cause bacteraemia with or without the development of intra-abdominal abscesses and pain in the right lower quadrant that mimics acute appendicitis. Although *Y. enterocolitica* produces enterotoxin, this does not contribute to the pathogenicity which is due to plasmid-encoded proteins of the outer membrane of the organism, responsible for the mucosal adherence and invasion. Antibodies directed against these proteins are present in patients convalescing from disease.

Diagnosis

The diagnosis is established by recovery of the organism from the stool. However, in patients with chronic disease, radiological investigation may show nodular filling defects in the terminal ileum which may simulate Crohn's disease. When operation is carried out the terminal ileum and mesenteric lymph nodes are found to be inflamed and swollen. Biopsy of the lymph nodes for *Yersinia* may be performed with safety in these patients, but an appendicectomy is ill advised.

Clinical features

Y. enterocolitica infections are more common in cold climates and hence prevalent in northern Europe. The incubation period is 1–14 days but the duration of stool excretion of the organisms is much longer (up to 3 months). The majority (75%) of patients are children aged 5–15 years. The spectrum of disease ranges from asymptomatic to an acute self-limiting gastroenteritis to life-threatening sepsis especially in infants.

The most usual clinical syndrome is an acute febrile gastroenteritis which is self-limiting lasting 5–14 days. However, chronic symptoms including diarrhoea and rectal bleeding may occur that are associated with persistent inflammation, particularly in children. Several syndromes are associated with *Yersinia* infection in children. These include enterocolitis, the pseudoappendicitis syndrome, bacteraemia and postinfectious sequelae.

Enterocolitis

This is the most common presentation and occurs primarily in young children (mean age of 24 months). The incubation period is 4–6 days, with a range of 1–14 days. The prodromal symptoms include listlessness, anorexia and headache which are followed by watery, mucoid diarrhoea, fever, colicky abdominal pain and bloody stools. The diarrhoea may be short lived but may also last a few weeks. Concomitant bacteraemia occurs in 20–30% of infants younger than 3 months. Most cases are self-limited. Complications include diffuse ulceration and inflammation of the small intestine and colon, peritonitis, meningitis, intussusception and cholangitis.

Pseudoappendicitis syndrome

This is characterized by fever, abdominal pain, tenderness in the right lower quadrant and leucocytosis and is usually caused by *Y. pseudotuberculosis*. The infection causes mesenteric lymphadenitis with terminal ileitis. The pseudoappendicitis syndrome is more common in older children and young adults.

Bacteraemia

Bacteraemia is seen most frequently in very young infants and patients with iron-overload syndromes receiving frequent transfusion (sickle cell anaemia, thalassaemia) and in patients on oral iron supplements.

Postinfectious, non-suppurative sequelae

Although uncommon, these may cause considerable morbidity. They include reactive polyarthritis, erythema nodosum and proliferative glomerulonephritis. They are usually encountered in individuals with HLA-B27. Chronic inflammatory bowel disease has also been associated with *Y. enterocolitica* infections.

Treatment

In mild disease, treatment is primarily supportive with fluid and electrolyte therapy. Antibiotics do not influence the course of uncomplicated enteritis. However infants younger than 3 months and immunocompromised children require aggressive in-hospital treatment with intravenous antibiotics. Tetracycline has been traditionally the drug of choice. However, with the increasing resistance to this antibiotic and its inadvisability in children younger than 8 years, alternative first-line drugs which include aminoglycosides and trimethoprim-sulfamethoxazole are used nowadays. Other effective drugs include third-generation cephalosporins and chloramphenicol. Antimotility agents are contraindicated in the treatment of *Y. enterocolitica* infection because of the increased risk of invasion.

Typhoid fever (enteric fever)

Typhoid fever (enteric fever) is a serious potentially life-threatening multisystemic infection caused primarily by *Salmonella typhi*. The disease is prevalent in conditions of poor sanitation and overcrowding and is endemic in developing countries. Typhoid fever is characterized by an early septicaemic phase with colonization of several organs, i.e. liver, spleen, bones and small intestine. The classic presentation is with fever, malaise, diffuse abdominal pain and constipation. However, the disease is known for its protean manifestations, such that it often poses a diagnostic challenge. Survivors may be left with long-term or permanent neuropsychiatric complications or a chronic carrier state. The terminal ileum in the region of the Peyer's patches is the commonest site for intestinal infection with the formation of longitudinal ulcer(s) on the antimesenteric border situated within 45 cm of the ileocaecal valve in the majority of patients.

Pathophysiology

Typhoid fever is transmitted by the oral route (contaminated food including chicken and shell fish and drinks) or because of poor personal hygiene resulting in hand-to-mouth transmission following contamination from toilet seats. Whatever the route, only a small inoculum (100 000 organisms) is required for contracting the disease by this highly pathogenic organism.

Following ingestion non-typhoid *Salmonella* organisms are promptly phagocytosed by luminal macrophages, which then pass them through the intestinal mucosa. The macrophages recognize the pathogen-associated molecular patterns (PAMPs) and lipopolysaccharides by their special receptors and are thus able to recruit (by the release of IL-8) T-cells and neutrophils to mount an inflammatory response designed to protect the host. The situation is different for *S. typhi*, which enters the host primarily through the distal ileum using specialized fimbriae that adhere to the mucosal epithelium covering the Peyer's patches which serve as the main staging point for macrophages carrying *S. typhi* entering from the gut lumen. However, *S. typhi* has a Vi capsular antigen that masks PAMPs, avoiding the host defensive neutrophil-based inflammatory response. The organism is thus able to replicate within the macrophages as these reach the mesenteric lymph nodes and then through the thoracic duct and other lymph channels to the reticuloendothelial tissues of the liver, spleen, bone marrow and lymph nodes. Once there, the *S. typhi* bacteria continue to multiply to reach a critical density when they induce macrophage apoptosis, and are thus released and able to invade the bloodstream (bacteraemia) and establish the full-blown disease. The gallbladder is infected either by the bacteraemia or direct by extension from infected bile. *S. typhi* is thus able to re-enter the gut to reinfect the Peyer's patches. Some bacteria are shed in the stool and become a source for infection of other hosts.

Clinical features

The disease occurs sporadically in Western countries but is endemic in Asia, Africa, Latin America, the Caribbean, Oceania, Bangladesh, China, India, Indonesia, Laos, Nepal, Pakistan, and Vietnam. Within these countries, typhoid fever is prevalent in poor underdeveloped regions. Worldwide, the majority of typhoid fever cases involve school-aged children and young adults, although no age group is exempt. In children, the clinical picture may be atypical, ranging from a mild febrile illness to severe convulsions.

The classical presentation of typhoid fever after an incubation period of 7–14 days begins with a rising 'step-wise' temperature during the day that remits by the subsequent morning, although in recent years this remittent temperature is encountered less often. The patients then develop diffuse abdominal pain and tenderness during the first week of the illness. In some patients, the pain is diffuse, severe and colicky; in others it is constant and located in the right upper quadrant. The swelling of the Peyer's patches due to the inflammation narrows the bowel lumen, and is thought to be the cause of the constipation that characterizes the classical presentation of typhoid fever. As the disease progresses other symptoms develop, including dry cough, malaise, frontal headache, diminished consciousness and even delirium. The fever reaches a plateau of 39–40°C at the end of the first week, when typical pink 'rose spots' develop over the trunk but are usually few in number. They are caused by dermal bacterial emboli and resolve within a few days.

Abdominal distension and splenomegaly develop in the second week. At this stage, some patients may develop a bradycardia and a dicrotic pulse; they remain febrile and become more toxic and anorexic during the third week. Respiratory signs include tachypnoea and crepitations over the lung bases. Abdominal distension increases and may be accompanied in some patients by foul smelling, green liquid diarrhoea (pea soup diarrhoea) as the patient deteriorates to the 'typhoid state', characterized by apathy, confusion, and delirium. Rectal bleeding may also occur. Death is caused by overwhelming toxaemia and myocarditis with sudden death. A percentage of patients who survive the disease become *S. typhi* carriers forming a potential source of transmission of the disease to others, although asymptomatic carriers of *S. typhi* who have not had the disease are well documented.

The above classical picture may be absent. In the first instance, the 'stepladder' fever pattern previously considered the hallmark of typhoid fever is rarely encountered nowadays. Instead, the fever has an insidious onset and is steady. Also children and immunosuppressed individuals develop diarrhoea rather than constipation. Other atypical manifestations include severe headaches mimicking meningitis, acute lobar pneumonia, isolated infections, severe jaundice or pyrexia of unknown origin. In some countries, such as India and Africa, patients often present with neurological manifestations, e.g. delirium, parkinsonian symptoms or Guillain–Barré syndrome. When perforation of the terminal ileum occurs, the patient will develop severe lower abdominal pain and will have obvious signs of peritonitis on examination.

Diagnosis

Diagnosis is based on identifying the organism which can usually be found in faeces and urine in the second week. During the first week, blood culture and bone marrow culture may be positive. Liver function tests are often abnormal and, if perforation has occurred, a chest radiograph may show gas under the diaphragm. Serology (Widal's reaction) is of little value in the tropics as antibodies will be present from previous clinical or subclinical infection.

Complications

The main complication is perforation of the terminal ileum. This is solitary in 85% of cases and the incidence of perforation varies considerably from one endemic area to another. It is high in West Africa (15–33%) and low in Egypt and Iran (1–3%). The high incidence of perforation in West Africa has been attributed to late diagnosis and a particularly virulent strain of organism. The perforation is caused by necrosis of the Peyer's patches. Perforation is often unheralded and may be masked by corticosteroids (see Treatment). The other complications include intestinal haemorrhage and, rarely, pancreatitis, meningitis, orchitis, osteomyelitis and abscess formation anywhere on the body.

Treatment

The modern treatment of typhoid fever is governed by the following important considerations: (1) early diagnosis and antibiotic therapy curtails the severity of the disease and its course, (2) multidrug resistance to the antibiotics is an increasing problem and (3) the pattern of antibiotic resistance varies with the geographical area in which the disease is contracted. With prompt and appropriate antibiotic therapy (depending on best guess started before culture and sensitivity results become available), typhoid fever should be curtailed to a relatively short-term febrile illness requiring a median of 6 days of hospitalization, with few long-term sequelae and a low (0.2%) mortality.

Patients in Western countries with suggestive symptoms developing within 60 days of a visit to an overseas endemic area or those following consumption of contaminated food/drink should be started on the best-guess antibiotic therapy. The antibiotic regimen may need to be changed after the results of culture and sensitivity become available.

Previously healthy patients who remain in good condition with uncomplicated disease may be treated as outpatients but advised to use strict hand washing techniques and to avoid handling/preparing food for others. All other patients including children should be hospitalized and nursed in isolation during the acute phase of the infection with safe disposal of excreta (faeces and urine). Ill patients are best given intravenous fluids and electrolytes until the condition improves. Oral fluids and a soft low-residue digestible diet are commenced in the absence of ileus and distension.

Antibiotic therapy

Although the WHO guidelines recommend fluoroquinolone treatment for both complicated and uncomplicated cases of typhoid fever, most experts now consider these guidelines to be no longer applicable in view of the increasing resistance of *S. typhi* (up to 38%) in some countries to fluoroquinolones. The current recommendation is that the sensitivity pattern of *S. typhi* in the area of acquisition is the only valid criterion for choice of the antibiotic from the following, depending on the reported resistance in the area of acquisition of the infection:

- chloramphenicol (Chloromycetin) orally or intravenously
- amoxicillin administered orally
- trimethoprim and sulfamethoxazole administered orally
- ciprofloxacin and other quinolones (ofloxacin, norfloxacin, pefloxacin) [not currently recommended in children and pregnant women (induces cartilage damage)]
- gatifloxacin (third-generation fluoroquinolone)
- azithromycin (Zithromax) often used in children
- cephixime
- ceftriaxone (third-generation cephalosporin).

Chloramphenicol was used to treat typhoid until the 1970s, when widespread resistance developed. Ampicillin and trimethoprim-sulfamethoxazole were then used instead until the late 1980s, when some *S. typhi* and *S. paratyphi* strains developed plasmid-mediated resistance to all three antibiotics agents (multidrug resistant).

The third-generation cephalosporins have been used in regions with high fluoroquinolone resistance rates (Asia and Vietnam). Even so, in these countries sporadic resistance to cephalosporins has been reported. The third-generation fluoroquinolone, gatifloxacin, is highly effective against all known clinical strains of *S. typhi* both *in vitro* and *in vivo* and to date gatifloxacin-resistant strains have not been reported, although they are likely to be encountered in the future.

The guidelines of the Indian Association of Paediatrics (IAP) issued in 2006 recommend cefixime as the initial best-guess therapy for uncomplicated typhoid fever with azithromycin as the second-line antibiotic. For complicated typhoid fever, IAP recommends ceftriaxone with aztreonam and imipenem as second-line agents for complicated cases. In sub-Saharan Africa and the Middle East, the rate of resistance to fluoroquinolones remains relatively low and thus, in these regions, the initial treatment is with oral ciprofloxacin for uncomplicated disease and intravenous ciprofloxacin for severe or complicated infections. In randomized controlled trial, dexamethasone has been shown to decrease mortality (from 55% to 10%) in severe typhoid fever cases complicated by delirium, obtundation, stupor, coma or shock.

Surgical treatment

Surgical treatment is reserved for complications which most commonly include ileal perforation with peritonitis, intra-abdominal abscesses and much less commonly gangrenous typhoid cholecystitis. The surgery is undertaken under intravenous anti-*S. typhi* antibiotic cover and includes thorough cleansing of the peritoneal cavity and suture of the perforation with drainage. The edges of the perforation are trimmed before closure. Small bowel resection is indicated only for patients with multiple ileal perforations. If antibiotic treatment fails to eradicate the hepatobiliary carriage, then a cholecystectomy is indicated; however cholecystectomy is not always successful in eradicating the carrier state because of persisting hepatic infection.

Gastrointestinal (abdominal) tuberculosis

Worldwide, TB causes 3 million deaths annually and, approximately, one-third of the world's population is infected with the TB bacillus, although many such individuals do not develop clinical disease unless the immune system becomes depressed by disease such as HIV infection or immunosuppressive drugs and old age. Gastrointestinal TB has become a major health problem in both developed and underdeveloped countries. The recent significant increased incidence in Western countries has been the consequence of the HIV pandemic and increased immigration from countries with high prevalence of TB. Another important change concerns the reduced association between pulmonary and intestinal disease, such that only a minority of patients (<20–25%) with abdominal TB have abnormal chest radiographs indicative of active or healed pulmonary disease. Although gastrointestinal TB may affect any part of the gastrointestinal tract, including the oesophagus, the majority of infections involve the ileum and colon. The diagnosis of abdominal TB often proves difficult. In practice it is based on the demonstration of acid-fast bacilli, caseating or non-caseating epithelioid cell granulomas on histology, evidence of TB at other sites, and, in some cases, on complete response to antituberculous therapy. Multidrug-resistant TB is an increasing problem and, when present, more than doubles the 1 year mortality (from 20% to 50%).

Pathology

The disease is caused by *Mycobacterium tuberculosis*. The routes of gastrointestinal infection are (1) ingestion of infected sputum by patients with active pulmonary TB, especially those with pulmonary cavitation and positive sputum smears; (2) spread by haematogenous route from pulmonary tuberculous to mesenteric and submucosal lymph nodes; and (3) local spread from intra-abdominal organs involved by primary tuberculous infection (renal TB).

Pathologically gastrointestinal TB is characterized by inflammation and fibrosis of the bowel wall and the regional lymph nodes. Mucosal ulceration results from necrosis of Peyer's patches and from vascular thrombosis. At this stage of the disease, the pathological changes are reversible with antituberculous therapy and healing without scarring is possible. However, with progress of the disease, the ulcers become confluent and the continued tissue damage leads to extensive fibrosis with thickening of the bowel wall and the formation of pseudotumoral mass lesions. Strictures and fistula formation may also occur. The serosal surface of the bowel may exhibit nodular masses or miliary tubercles. The mucosa is inflamed with hyperaemia and oedema similar to that encountered in Crohn's disease but short of the classical cobblestone appearance. Aphthous ulcers may develop in the colon in some patients. Caseation is not always present in the bowel wall but is almost universally present in the regional lymph nodes. Various types of granulomas are seen on histology: caseating, non-caseating, confluent, discrete and suppurative. Granulomas are most commonly found in the submucosal layer in association with a predominant lymphoplasmacytic inflammation in the lamina propria. Both intestinal perforation and bowel ischaemia may occur.

Intestinal TB can be classified into three macroscopic forms.

1. The ulcerative form (60%) – multiple superficial ulcers largely confined to the epithelial surface with their long axis lying perpendicular to the long axis of the bowel.
2. The hypertrophic form (10%) – causes thickening of the bowel wall with scarring, fibrosis, producing a firm matted mass which may simulate a carcinoma.
3. The ulcerohypertrophic form (30% of patients) – with features of both the ulcerative and hypertrophic forms.

The *hypertrophic type* affects predominantly the ileocaecal region and is characterized by the absence of gross caseation but with marked thickening of the submucosal and subserosal layers. It can also involve the ascending and transverse colon and is generally regarded as a low-virulence infection in a patient with a high degree of immunological resistance from previous exposure.

The *ulcerative type* affects predominantly the terminal ileum where multiple deep ulcers develop and extend to the serosa and may give rise to perforation. The serosal surface is thickened and studded with tubercles. Healing may result in multiple strictures with intervening dilated segments of ileum. Bacterial overgrowth may develop at this stage and cause diarrhoea and malabsorption. The *hypertrophic variety* is the least common and causes extensive matting of the small intestine and colon with considerable fibrosis and thickening.

Clinical features

Intestinal TB can occur in persons of any age, although it is more common in children and in older people. The ileum is more commonly involved than the jejunum and ileocaecal involvement is encountered in 80–90% of patients, presumably because of the abundant lymphoid tissue (Peyer's patches). Proximal (jejunal) small intestinal disease is seen more commonly with *M. avium intracellulare* complex infection. Intestinal obstruction when it occurs may be partial or complete. Segmental involvement causes the stenotic form of the disease. A recent report identified type II diabetes mellitus (23%) and alcoholism (23%) as the main comorbid disorders associated with abdominal TB.

Non-specific symptoms such as weight loss and abdominal pain are present in 80–90% of patients. Approximately 30% of patients have constipation. Nausea and vomiting may indicate the presence of subacute intestinal obstruction. The more specific clinical features of abdominal TB include abdominal pain, weight loss, anaemia and fever with night sweats.

Others present with a tender palpable mass in the right iliac fossa. Some patients may present acutely with symptoms of intestinal obstruction or acute right iliac fossa pain. Other acute presentations include haemorrhage and perforation, although free perforation is rare. Malabsorption is common and may be caused by subacute obstruction leading to bacterial overgrowth, but may be due to other causes including involvement of the mesenteric lymphatic system (tabes mesenterica) which may impair chylomicron transport resulting in steatorrhoea.

The physical signs include reduced muscle mass, abdominal tenderness, ascites, abdominal gaseous distension (subacute obstruction), abdominal mass (usually in the right iliac fossa) but may be felt elsewhere (omental cakes).

Diagnosis

The diagnosis of abdominal TB often poses difficulties even in endemic areas. This is documented by postmortem reports of patients in whom abdominal TB is diagnosed only after death. In essence the diagnosis of abdominal TB can only be firmly established by demonstrating acid-fast bacilli on smear or positive mycobacterial culture from the tissue or by demonstrating caseating granulomas by histological examination. The problem is, however, that abdominal TB is paucibacillary. In practice, the diagnosis requires a high index of suspicion in all cases together with a battery of laboratory, haematological, imaging and endoscopy tests. Even so, cases are encountered when despite strong clinical suspicion all the available tests are inconclusive. In these situations, provided malignancy can be excluded with reasonable certainty, a therapeutic trial of antituberculous therapy may be justified. However, laparotomy is indicated where malignancy cannot be ruled out. In these cases, a frozen section is recommended and a mesenteric lymph node should be removed for both culture and histology (caseating granulomas). Likewise, ascitic fluid should be sampled for staining for acid-fast bacilli and culture/guinea pig inoculation.

Attempts should be made to culture the mycobacterium from gastric washings, faeces, peritoneal fluid and tissue biopsies including enlarged peripheral lymph nodes. It is important to realize, however, that certain atypical mycobacteria (not responsible for TB) may be demonstrated in certain chronic inflammatory conditions including Crohn's disease. Haematological tests show non-specific changes of anaemia, hypoalbuminaemia and elevated ESR, but these are unhelpful in establishing the diagnosis. Likewise, the tuberculin test even when positive is unhelpful as it does not differentiate between an active and inactive disease. The serological tests: soluble antigen fluorescent antibody (SAFA) and enzyme-linked immunosorbent assay (ELISA) lack sensitivity and specificity. At best, they only suggest a probable diagnosis.

A recently developed RD-1 gene-based assay (the PBMC ELISPOT assay) for diagnosing TB infection shows promising results with a reported sensitivity and specificity of 89% and 78%, respectively. In patients with tuberculous ascites, sampling of the peritoneal fluid may be helpful if it contains $>30\,g/L$ protein and $>1000/mm^3$ (mostly lymphocytes), an ascitic/blood glucose ratio of <0.96, and adenosine deaminase levels of $>33\,IU/mL$. Acid-fast bacilli are rarely seen on smears but may be cultured from the ascitic fluid, especially after concentration by centrifugation prior to culture.

Imaging tests

- *Plain radiograph of the abdomen* is useful in patients with intestinal obstruction and perforation. It may also show calcification in lymph nodes. A chest radiograph is needed in all patients for evidence of active or healed pulmonary infection.
- *Barium contrast studies (follow-through or small bowel enema)* are very useful in suspected gastrointestinal TB as they can demonstrate bowel lesions such as multiple strictures. The other radiological findings identified by double contrast studies are mucosal irregularity, flocculation and fragmentation of barium (malabsorption), dilated, displaced (enlarged lymph nodes) and adherent fixed small bowel loops. Thickening of the ileocaecal valve lips and/or a wide gaping valve with narrowing of the terminal ileum (Fleischner sign) is said to be characteristic of TB. The mucosal ulcers seen with double contrast studies are initially shallow with elevated margins but become confluent as the disease progresses. The ulcers are typically perpendicular to the long axis of the bowel and their healing causes annular strictures. Although these findings are similar to those encountered in Crohn's disease, the cobblestone appearance is not encountered in intestinal TB. Ileocaecal TB is characterized by a deformed, narrow, irregular and short upwardly displaced caecum, with an incompetent ileocaecal valve, dilated ileum, an increased ileocaecal angle and shortened ascending colon.
- *Ultrasonography* is useful in demonstrating the presence of even small quantities of ascitic fluid and may detect peritoneal disease. The reported ultrasound findings include multiple, thin complete and incomplete septae and visible echogenic debris (high fibrin content of the ascitic fluid). Peritoneal thickening and nodularity are the other sonographic features of abdominal TB. Omental cakes and adhesions can also be detected but not peritoneal tubercles. Lymphadenopathy is seen as conglomerate masses and/or as scattered enlarged nodes with hypoechoic or anechoic centres from necrosis. Thickening of the SBM $\leq 15\,mm$ and increased mesenteric echogenicity combined with mesenteric lymphadenopathy are recognized characteristic sonographic features of early abdominal TB. Ultrasonography may also be useful for guiding ascitic fluid sampling and fine-needle aspiration cytology of lymph nodes/hypertrophic lesions.
- *Computed tomography:* the common findings on CT suggestive of abdominal TB are high-density ascites, lymphadenopathy, bowel wall thickening and irregular soft-tissue densities in the omental region. Abdominal lymphadenopathy is the commonest manifestation of abdominal TB on CT scanning. The lymph nodes involved most commonly include mesenteric, periportal, peripancreatic and upper para-aortic groups of nodes. Tuberculous lymphadenopathy commonly shows peripheral rim enhancement, frequently with a multilocular appearance, as distinct from lymphomatous adenopathy which typically exhibits homogeneous attenuation.
- The CT features that can help to distinguish tuberculous peritonitis from peritoneal carcinomatosis include a smooth peritoneum with minimal thickening and marked enhancement after contrast in TB as opposed to a nodular and irregular peritoneal thickening in peritoneal carcinomatosis.
- Comparative studies between CT and ultrasonography for the diagnosis of abdominal TB have shown that CT is more accurate than ultrasound

in detecting abnormalities such as periportal and peripancreatic lymph nodes and bowel wall thickening as, in contrast to ultrasound, there is no disturbance by bowel gas. However, bowel wall dilatation is better defined by ultrasound. Thus although CT is more sensitive and specific, ultrasound has the advantage of being less expensive, widely available, and easy to perform.

Endoscopy and laparoscopy

All types, upper gastrointestinal, colonoscopy, balloon enteroscopy and small bowel CE, have been used in the attempt to confirm the diagnosis. Endoscopic appearances in TB include hyperaemic nodular friable mucosa, irregular ulcers with sharply defined margins and pseudopolyps. It is important to stress that endoscopic biopsy which should always be performed may not reveal granulomas as these lesions occur most commonly in the submucosal layer although multiple biopsies from the same site may increase the yield. Endoscopic biopsy specimens may be subjected to polymerase chain reaction for detection of acud-fast bacilli.

Laparoscopy is invaluable and should always be undertaken in cases where the standard tests are inconclusive. The laparoscopic appearances of abdominal/peritoneal TB are virtually diagnostic: thickened peritoneum, multiple yellowish white/grey miliary tubercles studded over the parietal and visceral peritoneal surfaces. Some reports suggest that these appearances are more helpful in diagnosis of TB than either histological or bacteriological examination. Laparoscopy also enables procurement of tissue and fluid samples for laboratory and histological testing.

Treatment

All patients with abdominal TB are treated with a full course of antituberculous therapy using first-line drugs for 12–18 months, although some reported series have used shorter regimens lasting for 6–9 months with reported equally efficacy and increased compliance. Some recommend the addition of corticosteroids in patients with peritoneal disease in an attempt to reduce adhesive complications including sterility in females although there are no randomized controlled trials to confirm the efficacy of steroids.

Antituberculous drugs and regimens

The drugs are categorized as (1) *first-line drugs*, which are used in various combinations in the first instance; (2) *second-line drugs*, defined as such because they are less effective than the first-line drugs, or because they are more toxic or because they are unavailable in many developing countries; (3) *third-line drugs*, which are not on the WHO list either because they are not very effective or because their efficacy has not been proven with the exception of rifabutin (proven efficacy) but which is not included on the WHO list as it is considered too expensive for most developing countries.

All first-line antituberculous drugs have standard abbreviations:

- ethambutol is EMB or E
- isoniazid is INH or H
- pyrazinamide is PZA or Z
- rifampicin is RMP or R
- streptomycin is STM or S.

Drug regimens are also abbreviated: the drugs are listed using their single letter abbreviations. A *prefix* denotes the *number of months* of the treatment. A *subscript* denotes intermittent dosing (thus $_3$ = three times a week) and *no subscript* means daily dosing. Most regimens have an initial high-intensity phase, followed by a continuation phase (consolidation or eradication phase).

The regimens currently recommended are:

- 2HREZ/4HR = 2 months of izoniazid, rifampicin, ethambutol and pyrazinimide followed by 4 months of isoniazid and rifampicin
- 2SHRZ/4HR = 2 months of streptomycin, isoniazid, rifampicin and pyrazinamide followed by 4 months of isoniazid and rifampicin.

The WHO also recommends a 6 month continuation phase of HR (isoniazid and rifampicin) if the patient is still culture positive after 2 months of treatment.

The second-line drugs used in antituberculous therapy are:

- aminoglycosides: e.g. amikacin (AMK), kanamycin (KM)
- polypeptides: e.g. capreomycin, viomycin, enviomycin
- fluoroquinolones: e.g. ciprofloxacin (CIP), levofloxacin, moxifloxacin (MXF)
- thioamides: e.g. ethionamide, prothionamide
- cycloserine (the only antibiotic in its class)
- p-aminosalicylic acid (PAS or P).

The second-line drugs which are not included by the WHO are:

- rifabutin
- macrolides: e.g. clarithromycin (CLR)
- linezolid (LZD)
- thioacetazone (T)
- thioridazine
- arginine
- vitamin D
- R207910.

Other important measures include improving the general nutritional status of the patients by a high-calorie high-protein diet, physical rest and correction of deficiencies including hypoalbuminaemia and anaemia.

Surgical management

Although patients with intestinal obstruction usually require surgical treatment, successful resolution can occur although this often requires prolonged antituberculous therapy. Subacute intestinal obstruction or acute-on-chronic obstruction responds usually to conservative management and provides time for adequate investigation of the patient, who can then be managed electively if necessary. However, emergency surgical intervention is necessary for full blown intestinal obstruction with gross distension and for peritonitis due to small bowel perforation.

Ileocaecal resection with right hemicolectomy and primary anastomosis is now the standard operation for ileocaecal disease and the results are excellent provided that chemotherapy is maintained for appropriately long periods of time after surgery. For disease in regions other than the terminal ileum and caecum, segmental resection of the bowel with end-to-end anastomosis is performed. More recently stricturoplasty has been introduced to deal with fibrotic strictures. Again this must be performed under antituberculous drug therapy which has to be continued for some time after surgery. Other procedures which may be necessary include drainage of tubo-ovarian abscesses with or without salpingo-oophorectomy, gastrojejunostomy for gastric outlet obstruction caused by retroperitoneal and gastroduodenal lymphadenopathy and biopsies including harvest of mesenteric lymph nodes.

Actinomycosis

Actinomycosis is caused by filamentous, Gram-positive, non-acid-fast bacteria which belong to the order of Actinomycetales (family Actinomycetaceae, genus *Actinomyces*). However, other organisms, e.g. *Propionibacterium, Actinobaculum* and *Bifidobacterium* may cause similar disease. *Actinomyces* organisms are anaerobic/microaerophilic exhibiting slow growth to form colonies with a characteristic 'molar tooth' appearance. The most commonly isolated pathogens are *Actinomyces israelii, Actinomyces gerencseriae, Actinomyces turicensis, Actinomyces radingae* and *Actinomyces europaeus but several other species may cause the disease.* Nearly all actinomycotic lesions contain companion bacteria, the most important being *Actinobacillus actinomycetemcomitans, Peptostreptococcus, Bacteroides, Staphylococcus, Streptococcus* and Enterobacteriaceae, varying with the site of the disease. These companion pathogens enhance the low pathogenicity of actinomycetes. Actinomycosis is characterized by contiguous spread, suppurativa granulomatous inflammation, with the formation of multiple abscesses and sinus tracts which discharge 'sulphur granules'. The most common clinical forms of actinomycosis are cervicofacial, thoracic, abdominal and pelvic (in females).

Pathophysiology

Actinomycetes form part of the normal flora of the oral cavity, the lower gastrointestinal and the female genital tracts. The micro-organisms, because of their low virulence, require a break in the integrity of the mucous membranes and/or the presence of devitalized tissue to cause human disease. Actinomycosis is essentially a polymicrobial infection as it involves the co-operation of other bacterial species known as 'companion' pathogens which elaborate toxins that inhibit host defences. They are responsible for the early manifestations of the disease and may contribute resistance to antibiotic therapies.

Once infection is established, the host mounts an intense inflammatory suppurative, granulomatous response which is destructive and produces intense fibrosis. Actinomycosis spreads contiguously through tissue planes with direct involvement of tissues and organs in the path of the infection. The host response results in the formation of multiple abscesses which on bursting lead to sinuses discharging granular pus – the sulphur granules. Although lymphatic spread is unusual, haematogenous dissemination to distant organs may occur in any stage of the disease.

Cervicofacial actinomycosis

This is the most common type and accounts for 50–70% of reported cases. The infection typically occurs following oral extraction/surgery or in patients with poor dental hygiene. Initially, cervicofacial actinomycosis forms soft-tissue swelling of the perimandibular region. As the disease progresses, direct spread to the adjacent tissues occurs with the development of fistulas/sinuses discharging the typical yellowish pus containing sulphur granules. Direct invasion of the skull and bloodstream may occur in untreated cases.

Thoracic actinomycosis

Thoracic actinomycosis is less common (15–20% of reported cases) and usually arises following inhalation of infected oropharyngeal secretions. Rarely, thoracic actinomycosis results from oesophageal perforation or from direct spread from the neck or abdomen, or via haematogenous spread. Thoracic actinomycosis forms a pulmonary infiltrate or mass, which can invade the pleura, pericardium and chest wall, ultimately leading to external pleurocutaneous fistulas discharging sulphur granules.

Actinomycosis of the abdomen and pelvis

Actinomycosis of the abdomen and pelvis accounts for 10–20% of reported cases. Typically, these patients have a history of emergency bowel surgery, e.g. perforated acute appendicitis, perforated colonic diverticulitis or perforation by ingested foreign bodies (chicken or fish bones). The most common site of the disease is the ileocaecal region with presentation as a slowly growing mass in the right iliac fossa which may simulate malignancy. Involvement of any abdominal organ and the abdominal wall occurs by direct spread, with eventual formation of peritoneocutaneous fistulas discharging pus. Pelvic actinomycosis most often results from infection of the uterus occurring in association with longstanding intrauterine contraceptive devices.

Clinical features

Actinomycosis occurs worldwide, but with higher prevalence rates in areas with low socioeconomic status and in individuals with poor dental hygiene. The disease can affect all ages, but most reported cases are in young to middle-aged adults. The clinical features of cervicofacial actinomycosis include history of dental extraction or trauma to the mouth in an individual with poor oral hygiene, dental caries, or periodontal disease; painless or less commonly painful soft-tissue swelling of the perimandibular region and fever. The nodular lesion(s) due to abscess formation are usually located at the angle of the jaw. These gradually increase in size and number, burst to form sinuses/fistulas which open and discharge pus through either the cheek or submandibular region. The nodules are tender initially but become non-tender on palpation as the diseased tissues harden from the dense fibrosis. The skin overlying the diseased tissues is red with bluish discoloration. The patient experiences difficult and painful chewing of food from involvement of muscles involved in mastication and this may progress to trismus.

Patients with thoracic actinomycosis, in addition to poor oral hygiene, are individuals at risk of inhalation, e.g. epileptics and chronic alcoholics. The established disease causes chest pain, a dry or productive cough and shortness of breath with fever, weight loss, fatigue and anorexia. Aside from fever, the other signs include cachexia, abnormal breath sounds and haemoptysis and the development of pleurocutaneous fistulas discharging the typical granular yellow pus.

In abdominal actinomycosis, there is nearly always a history of emergency abdominal operation. Examination reveals scar(s) from previous abdominal surgery, low-grade fever and cachexia together with a right lower quadrant mass which is firm-to-hard in consistency, non-tender and fixed to underlying tissues. Infection spreads mainly to the psoas muscle, abdominal wall and adjacent organs. Spread of the infection by the portal venous system results in multiple intercommunicating loculated abscesses (honeycomb liver). The clinical features also include low-grade fever, weight loss, fatigue, altered bowel habits, abdominal pain, nausea and vomiting, and a tender mass usually in the right iliac fossa with varying induration of the overlying skin and the eventual development of the characteristic discharging sinuses. Peritoneocutaneous fistulas may discharge pus on the anterior abdominal wall or the perianal region. In females with pelvic disease, the clinical features include lower abdominal discomfort, abnormal vaginal bleeding (meno/metrorrhagia) or discharge and pelvic mass.

Treatment

The majority of cases require only antibiotic therapy, although surgery may be required in selected cases: drainage of abscesses, excision of sinus tracts and dense fibrotic lesions, decompression of closed-space infections, and for the relief of obstruction most commonly to the ureter.

Penicillin G is the drug of choice. High-dose penicillin is administered over a period of 6–12 months. To a large extent, the duration of antibiotic therapy depends on the stage and extent of the disease. Thus shorter courses (<6 months) are used especially in cases of early cervicofacial actinomycosis with minimal disease. Thus the period of antibiotic therapy is tailored to the individual patient and is dictated by the clinical and radiographic response. The development of resistance to penicillin by actinomycetes is not a problem and lack of a clinical response to penicillin usually indicates resistance by the companion pathogens. This is the usual reason for change in the antibiotic regimen. Another frequent problem is allergy to penicillin which precludes its use.

The antibiotic regimens used in the absence of allergy to penicillin are:

- penicillin G: adult dose 12–24 million units daily intravenously by continuous infusion or in 4 hourly divided doses for 1–2 weeks, followed by oral penicillin VK for 6–12 months
- penicillin VK: adult dose 500 mg orally every 6 hours for 6–12 months.

In patients with penicillin allergy, the following antibiotics are used:

- doxycycline (Vibramycin): adult dose: 100 mg orally or intravenously every 12 hours
- clindamycin but this does not cover the companion pathogens. Adult dose: 600 mg intravenously every 8 hours

In patients with poor response due to resistance by copathogens, the following antibiotics may be used:

- amoxicillin/clavulanic acid (Augmentin): adult dose 500 mg orally every 8 hours or 875 mg orally every 12 hours
- ceftriaxone: adult dose 2 g intravenously or intramuscularly every 12–24 hours
- imipenem/cilastatin – useful in moderately severe to severe forms of abdominal and pelvic actinomycosis: adult dose 500–1000 mg intravenously every 8 hours.

HIV enteropathy

Gastrointestinal problems are extremely common in patients with AIDS (Box 29.2). In some of these patients, the symptoms are caused by opportunistic infection with protozoal organisms, various bacterial species, viruses and fungi or tumours.

However, in a significant percentage of patients (about 30%) no identifiable pathogens can be isolated from the stool. This indicates that HIV may cause a specific enteropathy and recent studies using DNA probes have identified the presence of HIV in the base of the crypts and in the lamina propria. HIV enteropathy is nowadays defined as a syndrome of chronic (more than 4 weeks' duration) severe watery diarrhoea occurring in HIV-positive patients without an identified infectious cause despite intensive investigation. This 'idiopathic' enteropathy is thought to be due to direct effects of the HIV on the enteric mucosa. The intestinal mucosal immune system is now known to be involved in the pathogenesis of AIDS, with key events of the disease (transmission, viral amplication, and destruction of CD4+ T-cells) taking place within the gastrointestinal tract.

Histologically, the enteropathy is characterized by lymphocytic infiltration of the mucosa with evidence of damage, including villous atrophy, crypt hyperplasia and villous blunting of the epithelial layer. These changes appear to result from a direct

toxic effect of the HIV on the enterocytes mediated by the HIV accessory protein *Tat* which inhibits glucose uptake by the enterocyte. Another HIV protein *gp120* decreases the ability of the gut mucosal cells to maintain ionic gradients. There is, in addition, activation of the immune system with high levels of proinflammatory mediators (IL-6, IL-10 and interferon-γ). The most significant change consists of the substantial loss of the CD4+ T cells and counts below 200 cells/μL are invariably associated with HIV enteropathy.

Clinical features

HIV enteropathy can develop in the acute phase of AIDS or present in patients with advanced disease. The enteropathy is characterized by severe watery diarrhoea associated with increased inflammation and gut permeability. Other gastrointestinal symptoms include weight loss, abdominal pain, fever, sore throat, lymphadenopathy, arthralgia and an erythematous, maculopapular rash.

To some extent, the clinical presentation of HIV-associated diarrhoea varies with the principal site of involvement of the gut. Thus small bowel diarrhoea tends to result in large bulky postprandial stools immediately after eating, and the individual may experience postprandial paraumbilical abdominal pain and weight loss. Moreover, the diarrhoea abates significantly with fasting. In contrast patients with large intestine diarrhoea (colitic diarrhoea) have frequent, small-volume stools, often containing visible blood and mucus. These individuals often complain of lower quadrant abdominal pain, and rectal urgency/tenesmus. However, mixed clinical pictures are common and it is often difficult to differentiate between small and large bowel disease.

Diagnosis

In AIDS patients who develop symptoms of enteropathy, the initial step is three consecutive stool cultures for *Salmonella*, *Shigella flexneri* and *C. jejuni*, in addition to assays for *Clostridium difficile* toxins. This is followed by upper gastrointestinal endoscopy and colonoscopy for inspection of the mucosa and for procurement of biopsy material. Biopsies are cultured for cytomegalovirus and mycobacteria, adenovirus and herpes simplex virus. Duodenal fluid samples are also examined for parasites.

The routine diagnosis of AIDS itself is based on the detection of antibodies to HIV. Following infection, antibodies to the various antigens associated with the virus often do not appear for about 6 weeks, so that there is a long window when an individual may be negative on antibody testing to HIV and yet still be infected. Other tests include detection of circulating viral p24 antigen and the use of polymerase chain reaction by which very small amounts of viral RNA in infected cells can be greatly amplified.

Treatment

If a specific infection is established treatment is directed to eradicating the organism responsible. Symptomatic relief can be obtained using non-specific antidiarrhoeal therapy. Patients will benefit from supportive therapy with rehydration and electrolyte supplements. In severe cases, total parenteral nutrition is indicated. Plasma or serum citrulline assays have been introduced as an accurate assessment of the enterocyte cell mass. Citrulline is a metabolite of glutamine and is synthesized by small bowel enterocytes. Citrulline plasma levels are not influenced by nutritional status, level of hypoalbuminaemia or inflammatory status but are elevated in the presence of significant renal failure (creatinine clearance of <30 mL/min) because citrulline is normally metabolized to arginine in the proximal convoluted tubules. In the absence of renal impairment, plasma citrulline assays thus provide a reliable measure of the disease severity in HIV enteropathy and of the need for parenteral nutrition which is indicated in patients with a citrulline level of <10 μmol/L.

Antiretroviral therapy (ART) reduces plasma viral loads with consequent increase in peripheral blood CD4+ T-cells. In HIV enteropathy ART is effective in decreasing the gastrointestinal symptoms. However, a decrease in viral replication and CD4+ T-cell reconstitution is seldom obtained with standard ART in small bowel HIV enteropathy, and a much better response in these patients is obtained with highly active antiretroviral therapy which results in much greater reconstitution (twofold) of CD4+ T-cells.

Parasitic infestations of the small bowel

Ascaris (roundworm)

This infestation occurs directly from person to person without an intermediate host. The responsible parasite is *Ascaris lumbricoides* which enters by the oral route. Ova which have a special lipid layer which resists acid digestion in the stomach remain viable in the soil for several months to years. Immediately after ingestion the larvae emerge from the egg and penetrate the duodenal wall to enter the bloodstream to reach the liver, heart and pulmonary circulation where they enter the pulmonary alveoli at approximately 3 weeks from ingestion. They are then coughed up to be swallowed into the gut where they mature as adult worms (up to 40 cm in length) in the jejunal lumen. Infestation with *A. lumbricoides* is endemic throughout the world but the highest rates are encountered in China, Southeast Asia, in coastal regions of West Africa and in central Africa. Risk factors include low socioeconomic class and poor sanitation.

Clinical features

Initially, the symptoms are caused by the larval migration especially to the lungs (wheezing, fever, cough, chest pain and dyspnoea) including established asthmatic attacks. Migration to other sites may cause other symptoms, e.g. skin rash, conjunctivitis and convulsions.

The symptoms caused by the adult worms include abdominal pain with colicky attacks, nausea, vomiting, anorexia, weight loss, diarrhoea, malabsorption and anal itching. However, many infested individuals remain asymptomatic although they are at risk from complications which include intestinal distension and obstruction with vomiting (sometime of worms) and colicky abdominal pain, intestinal perforation with peritonitis, appendicitis, acute pancreatitis, volvulus, cholangitis and liver abscess.

Diagnosis

The diagnosis is made by demonstrating ova in a faecal sample, although adult worms are sometimes passed per rectum the worms may be seen on a small bowel follow-through. A full blood count may reveal eosinophilia and usually anaemia. Hypoalbuminaemia is frequent and the liver function tests may reveal evidence of liver damage. Other tests may be needed depending on the clinical picture including endoscopic retrograde cholangiopancreatography (ERCP) if involvement of the biliopancreatic tree is suspected.

Treatment

Eradication treatment is usually with one of the benzimidazole compounds such as mebendazole or albendazole or piperazine. Surgery is indicated for intestinal obstruction which does not resolve on conservative measures. At operation an attempt should be made to manipulate the mass of tangled worms into the caecum. If this fails, it may be necessary to extract the worm bolus via an enterotomy. Occasionally, a resection may be necessary if the viability of the bowel is in any doubt or if a perforation has occurred.

Mebendazole has a cure rate of 76–95% and is used as the first-line treatment of choice for adults and children over the age of 2. In some regions where mebendazole has been used for long periods, resistance to the drug has been reported. Piperazine is used in children (between 3 months and 2 years) but can also be used as an alternative to mebendazole in adults usually combined with a purgative (senna) to ensure complete expulsion. This regimen has been reported to be successful in relieving intestinal obstruction, thereby avoiding an operation, and can be instilled in the bile duct during ERCP in patients with biliary ascariasis.

Levamisole (nicotinic acid antagonist) is highly effective and is given as a single dose.

Ancylostomiasis (hookworm)

Ancylostomiasis is endemic in most tropical countries. It is caused by two filarial worms, *Ancylostoma duodenale* and *Necator americanus*. The larvae enter the body by penetrating into skin, usually the sole of the foot, forming an itchy lesion. The larvae enter the bloodstream to reach the lungs and through the alveoli, the tracheobronchial tree from which they ascend to the laryngopharynx where they are swallowed. *A. duodenale* can also be acquired by eating the raw or undercooked flesh of infected animals as larvae can penetrate the skin of various animals and survive in their muscle tissue.

The adult worm lives attached by hooks to the mucosa of the jejunum and ova are excreted in the faeces. Larvae develop from the eggs deposited on the soil in about 1 week. Infection is contracted by treading on the larvae during bare foot walking. The warm humid environment in mines enables the survival of hookworm larvae for long periods and accounts for the high prevalence of ancylostomiasis in miners in whom it is sometimes referred to as 'miners' anaemia.

Clinical features

Infestation may be associated with severe dyspepsia and gastrointestinal bleeding causing a microcytic anaemia and frank gastrointestinal haemorrhage especially in children. However, ancylostomiasis can produce minimal symptoms if the infestation is mild and indeed the disease may be asymptomatic if only a few worms are present. Symptoms are usually present in patients with longstanding infestations with high worm loads. They include asthenia, tiredness, weight loss and weakness in association with iron-deficiency anaemia. More severe symptoms, e.g. abdominal pain, overt malnutrition, bloody diarrhoea and heart failure, are well documented. To some extent, the range and severity of symptoms vary widely and depend on the nutritional status and overall general health of the patient, the species of worm and the extent of infestation.

Diagnosis

The diagnosis is made by the identification of ova in the faeces or adult worms in duodenal or jejunal fluid. A peripheral blood eosinophilia may occur during the invasive stage.

Treatment

The first stage of treatment is the correction of anaemia using either oral or injectable iron. Benzimidazole compounds, mebendazole or albendazole or pyrantel pamoate are used to clear the infestation.

Small bowel conditions causing malabsorption

Small bowel bacterial overgrowth

In this syndrome, also known as dysbiosis, the small intestine becomes colonized by bacteria with an increase in the concentration of organisms which are usually confined to the lower small bowel and the colon. This is usually caused by surgery or disease which results in excess bacteria entering the small intestine, or from delayed clearance of bacteria due to stasis (stagnant or blind loop syndrome). The various causes of bacterial overgrowth include:

- excessive entry of bacteria into the small intestine
  - achlorhydria – absence of bactericidal gastric HCl
  - gastrojejunostomy
  - partial/total gastrectomy
  - entercolic fistulas
  - cholangitis
  - loss of ileocaecal valve following right hemicolectomy
- intestinal stasis
  - Crohn's disease – stenosis
  - TB – stenosis
  - small bowel diverticulosis – stasis
- afferent loop stasis
  - enteroenteric anastomosis and other intestinal bypass procedures
  - subacute obstruction – adhesions, strictured anastomosis
  - blind loops
  - diabetes mellitus – autonomic neuropathy
  - radiation eneteritis – stenosis, impaired intestinal motility
  - scleroderma – impaired intestinal motility
  - amyloidosis.

In some cases bacterial overgrowth may develop in the absence of an obvious local cause particularly in patients with malnutrition or immune deficiency. There is also a growing body of research linking small bowel bacterial overgrowth (SBBO) with chronic fatigue syndrome, fibromyalgia and irritable bowel syndrome.

Pathophysiology

The bacterial overgrowth in the small intestine is usually in the order of 10^7 to 10^9 CFU/mL of intestinal contents. Bacterial colonization results in intestinal mucosal injury characterized by patchy inflammatory changes in the lamina propria which are accompanied by alterations in the concentrations of the brush border enzymes. The increased bacterial population deconjugates the intraluminal bile salts by removing the glycine or taurine moiety. In addition the bacteria dehydroxylate the steroid nucleus at the C7 position with the formation of deoxycholate and lithocholate which have a tendency to precipitate at the intraluminal pH levels of the small intestine. Thus these bile salts participate poorly in the emulsification of fat and they are passively absorbed to a limited extent by non-ionic diffusion through the small intestine. This leads to a net reduction of the concentration of effective bile salts in the lumen of the small bowel to levels below that required to form micelles. This in turn results in malabsorption of fats and fat-soluble vitamins.

The bacterial species which are responsible for bile salt deconjugation are eubacteria, bacteroides and corynebacteria. These bacteria also bind vitamin B_{12} and convert it to inactive derivatives (cobamides) which block the ileal receptors for the vitamin as well as for intrinsic factor. The resulting malabsorption of vitamin B_{12} may lead to megaloblastic anaemia. Often, however, the anaemia has a dimorphic picture because of an iron-deficiency component due to chronic blood loss from the primary lesion itself or from malabsorption of iron. Folate deficiency is rare as the bacteria synthesize folate in substantial amounts and some patients may in fact exhibit a high serum folate.

There is some malabsorption of carbohydrates and proteins although this is rarely significant. The main reason for malnutrition in patients with bacterial overgrowth is a diminished dietary intake, which accounts for growth retardation in children. The bacteria also metabolize triglycerides to free fatty acids which they hydoxylate to form hydroxy fatty acids. These impair the absorption of water in sodium by the intestinal mucosa of both the small and large intestine by acting as laxatives. This together with the action of the dehydroxylated bile salts, enterotoxin and osmotic load created by the fermentation of the major dietary components accounts for the diarrhoea which is seen in these patients.

Clinical features

The symptoms of bacterial overgrowth are varied. Initially the patients may exhibit symptoms referable to the underlying pathology, e.g. postgastrectomy symptoms or recurrent intestinal colic due to subacute obstructing lesions. Patients with jejunal diverticulosis (Figure 29.30) are symptomless until the onset of malabsorption, although they may occasionally develop unrelated complications such as gastrointestinal bleeding or perforation of one of the diverticula leading to generalized peritonitis. The symptoms and signs of bacterial overgrowth itself are often non-specific and include malaise, nausea and vomiting, excessive borborygmi and weight loss. Diarrhoea is extremely common and is usually watery but frank steatorrhoea with bulky pale offensive stools which are difficult to flush is less common.

Diagnosis

A full blood count is essential to assess the extent and type of anaemia which is often present in these patients. Estimations of urea and electrolytes, albumen and total protein levels are also important. The most useful test for assessing the presence of bacterial overgrowth, small bowel however, is the hydrogen breath test (see section small bowel investigations).

Complications

The complications of bacterial overgrowth include glossitis, stomatitis, anaemia, hypoproteinaemia with peripheral oedema, tetany, osteomalacia and rickets and growth retardation in children. Occasionally neurological manifestations such as paraesthesiae and peripheral neuropathy may be found in association with vitamin B_{12} deficiency.

Treatment

Surgical treatment of the underlying conditions wherever possible is the definitive and curative treatment. However, situations are frequently encountered where surgical treatment is

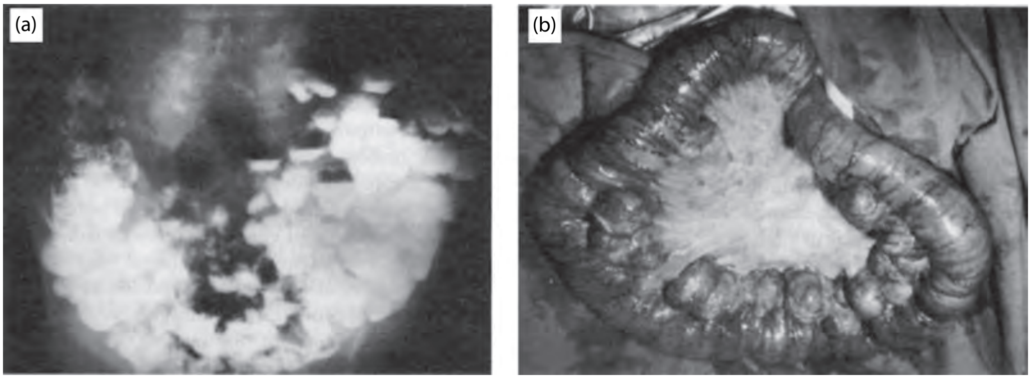

Figure 29.30 (a) Small bowel barium study showing extensive and multiple small bowel diverticula in a 65 year old woman with severe malabsorption. The steatorrhoea improved considerably with oral tetracycline therapy. (b) Multiple jejunal diverticula localized to a segment of the upper small intestine. The patient's bacterial overgrowth syndrome resolved after excision of the affected bowel.

not possible or advisable because of the extensive or systemic nature of the underlying disease, e.g. extensive jejunal diverticulosis and scleroderma. In these cases intermittent therapy with oral antibiotics is often beneficial. As control of the anaerobic organisms seems to be the most helpful objective, metronidazole is generally preferred, although tetracycline is also of value. A course of antibiotics is usually administered for about 2 weeks at a time and although repopulation of the intestine by bacteria occurs soon after discontinuation of the treatment, symptomatic improvement may last for several months. Intermittent therapy is therefore preferred to long-term management.

The treatment also includes dietary changes and the use of probiotics/prebiotics. The diet recommended in the treatment of SBBO is free of simple sugars and grains/cereals and low in fruit and starchy vegetables. This is thought to work by restricting the nutrition available for bacteria in the upper gastrointestinal tract and reduces the amounts of alcohol and organic acids produced by bacterial fermentation.

Specific therapy is with antibiotic medication together with natural antibiotic substances. Therapy usually requires several months to achieve control or reversal of the bacterial overgrowth of the small intestine. The antibiotics used are metronidazole, tetracycline and ciprofloxacin. In many ways all three have the potential to both cause and treat SBBO. The antibiotic used should target only the pathogenic bacteria without suppressing the beneficial flora. This is, however, more easily said than done. Metronidazole is the antibiotic of choice in most cases of SBBO. It is extremely effective against anaerobic bacteria but has little effect on aerobes. The most common side effects of metronidazole include nausea, diarrhoea and abdominal discomfort in addition to vaginal candidiasis in females. Thus metronidazole therapy is best accompanied by use of probiotics and of possibly antifungal agents.

Tetracycline is sometimes used when therapy with metronidazole is not successful. It is especially important to reinoculate the gut with probiotics when tetracycline is used. Ciprofloxacin is the most common drug used when the overgrowth is by aerobic bacteria. The side effects of this antibiotic include nausea, diarrhoea, abnormal liver function tests, vomiting and rash.

Probiotic bacteria

The most numerous probiotic bacteria present normally in the small bowel are species of lactobacilli (*Lactobacillus acidophilus*, *Lactobacillus rhamnosus*, *Lactobacillus bulgaricus*, etc.), whereas bifidobacteria (*Bifidobacterium bifidum*, *Bifidobacterium longum*, *Bifidobacterium infantis*, etc.) are the probiotics that predominate in the normal colon. Most of the probiotic products consist of one or more species of bacteria from these two groups. Lactobacilli impart considerable benefit to the gut by preventing overgrowth by pathogens, aid in the digestion of lactose and dairy products, improve nutrient absorption and maintain the integrity of the intestinal epithelium preventing access of macromolecules into the bloodstream.

Bifidobacteria also prevent colonization by pathogenic bacteria, maintain the low pH balance by production of acids, inhibit the growth of nitrate-forming bacteria, synthesize B-complex vitamins and help to regulate peristalsis.

Prebiotics

These are ingestible oligosaccharides which provide food and thus promote the growth of probiotic bacteria. They are present in certain fruits and vegetables, e.g. bananas, asparagus, garlic, onions, wheat, tomatoes, onions, etc. They are also available as supplements: fructo-oligosaccharides, galacto-oligosaccharides and inulin.

Short gut syndrome

This is the most serious form of intestinal decompensation and is encountered after extensive resection of the small bowel.

Pathophysiology

The outcome following intestinal resection depends on (1) the extent and site of resection, (2) the age of the patient and (3) the physical and mental condition of the patient.

The intestinal decompensation that follows massive resection of the small intestine is due to a sudden reduction of the absorptive area and a greatly reduced transit time which further aggravates malabsorption and in extreme cases limits the extent of digestion. Malabsorption of fats and proteins is invariably present but its severity varies with the length and site of the residual bowel. Carbohydrate absorption is less severely affected and is the first to return to normal in 4–6 weeks. The improvement in the absorptive capacity for protein is more gradual and the absorption of fats remains impaired at a fixed percentage. This is the result of interruption of the enterohepatic circulation of bile salts after ileal resection and a diminished bile salt pool, as the increased hepatic synthesis is unable to compensate for the large daily faecal losses.

Spillover into the colon of primary bile salt conjugates where bacterial action will convert them into deconjugated and dehydroxylated derivatives contributes to the diarrhoea which is characteristic of the short gut syndrome. This is because some of these secondary bile salts block the absorption of water and electrolytes by the colonic mucosa. The hydroxylation of the unabsorbed fatty acids by colonic bacteria has also been implicated in diarrhoea. The malabsorption of fats and fat-soluble vitamins is accompanied by the malabsorption of calcium and magnesium which are precipitated as soaps with the unabsorbed fatty acid. The severe diarrhoea which can amount to several litres in the first few weeks after resection is further aggravated by the low pH of the stool and often causes severe perianal irritation.

Lactose intolerance may occur in some patients after extensive small bowel resection and this has been attributed to a rapid transit time allowing insufficient time for lactase to act and to a reduction of the total intestinal lactase activity.

Aetiology

The aetiology is essentially extensive resection of small bowel for any of the following reasons:

- Crohn's disease
- mesenteric infarction
- radiation enteritis

- midgut volvulus
- multiple fistulas
- small bowel tumours.

Crohn's disease is by far the commonest cause as this often necessitates repeated resections over a number of years culminating in the short gut syndrome. Hence the reason for a conservative approach in these patients with limited resections and the judicious use of stricturoplasty for short fibrous strictures. While resection of more than half of the small bowel is frequently accompanied by serious malabsorption there is debate as to the extent of the small bowel resection which results in the short gut syndrome. An assessment of the length of the residual small bowel after resection is essential as there is a crucial length below which intestinal decompensation of varying degrees takes place. Patients with a residual small bowel length of less than 2 m have a diminished work capacity and those with less than 100 cm require home parenteral nutrition on an indefinite basis. Infants and neonates seem to tolerate extensive small bowel resections better than adults and a minimum of 30 cm of small intestine can support both nutrition and growth.

The critical length of residual small bowel necessary to prevent serious maldigestion and malabsorption depends on the site of resection and the retention or otherwise of the ileocaecal valve. Thus ileal resections are less well tolerated than jejunal resections, largely because the active transport sites for bile salts and vitamin B_{12} are localized in the ileum. Whenever possible, the surgeon should retain a terminal segment of ileum together with the ileocaecal valve. An intact ileocaecal valve slows the transit time and limits the degree of colonization of the residual intestine by an overgrowth of colonic bacteria.

Clinical features

The main clinical features are weight loss and diarrhoea which is watery and frequently copious. Because of diarrhoea and the low pH of the stool, perianal irritation is common. In patients who develop lactose intolerance the consumption of fresh milk is followed by attacks of abdominal pain and an increase in the severity of the diarrhoea. Other clinical features depend on the development of complications (see below).

Diagnosis

Diagnosis is made on clinical grounds with information on the extent of small bowel resection. Other tests of malabsorption (see section Small bowel investigations) are helpful in developing an objective assessment of the severity of the malabsorption.

Course of condition

With time, structural and functional changes occur in the residual bowel as part of the process of adaptation to the reduced absorptive area. In the human, the structural changes consist of dilation of the remaining intestine and enlargement of the villi. An increase in the length of the bowel has also been reported in the neonate. These structural changes are accompanied by a gradual improvement in the absorption of water, electrolytes, carbohydrates and protein. The enhanced absorption of water-soluble substances per unit length of intestine is not the result of greater absorption by individual cells but rather from an increased cell population in the intestinal villi. Both luminal and humoral factors are involved in this adaptive hyperplasia. The luminal factors include alimentary secretions and ingested nutrients. Duodenal juice may be particularly important as a source of epidermal growth factor. The maintenance of adequate intraluminal nutrition by the oral ingestion of appropriate food is essential for the adaptive response. Enteroglucagon is the most important humoral agent influencing the adaptive response. The stimulus for its release is thought to result from increased exposure of the residual bowel to luminal nutrition. The enteroglucagon then acts on the mucosal cells and stimulates an increased turnover of intracellular polyamines and cell growth. There is evidence however that the effect of intraluminal nutrition is also mediated through direct contact of the nutrients with the epithelial cells. Other factors which may contribute to compensation by the residual intestine include the changes in the motility pattern leading to a gradual slowing of the transit time and increased absorption of water-soluble substances by the colon.

In cases of mesenteric infarction varying amounts of colon are frequently resected with the small intestine. It is not known whether the extent of the associated colonic resection influences the clinical outcome but colonic mucosa does absorb water and salt and to a lesser extent glucose and amino acids. Some reports indicate that residual colon minimizes the severity of diarrhoea and may assume some of the absorptive functions of the small intestine.

Complications

The complications which can be associated with short gut syndrome include:

- gastric hypersecretion
- cholesterol gall stones
- hepatic disease
- impaired renal function and stone formation
- metabolic bone disease.

Gastric hypersecretion

Gastric hypersecretion occurs transiently and bears no relation to the extent of the intestinal excision although it appears to be more common after proximal resections. It is caused by an increased rate of basal acid secretion consequent on delayed clearance of gastrin. Around 50% of patients with extensive small bowel resection are affected.

Gall stone formation

There is a well-recognized increase in the incidence of gall stones after extensive ileal resection and jejunoileal bypass for morbid obesity. Cholesterol stones are the result of a reduced bile salt pool which leads to the bile becoming lithogenic, i.e. supersaturated with cholesterol which precipitates as cholesterol crystals. In addition however, pigment gall stones also occur after ileal resection.

Hepatic disease

Mild hyperbilirubinaemia, elevation of the serum transaminases and impaired excretion of BSP often occur after both massive intestinal resections and jejunoileal bypass. These are associated with fatty infiltration of the liver with or without hepatic atrophy. The increased deposition of fat in the liver after jejunoileal bypass occurs in patients while they are actively losing weight but not when the weight is stationary. Acute fulminant liver failure has been reported most commonly after jejunoileal bypass. The onset of the liver failure usually occurs within the first 6 months after operation and the clinical symptoms are those of a flu-like illness with anorexia, nausea, vomiting, rapid weight loss and a fall in the serum albumen. The onset of these manifestations is an indication for restoration of intestinal continuity. Cirrhosis may develop after jejunoileal bypass. Initially it causes no symptoms and its onset can only be detected by serial liver biopsies.

Impaired renal function and stone formation

The severe diarrhoea may lead to fluid and electrolyte losses and to a decrease in the glomerular filtration rate with a tendency to reduce urine output and concentrated urine. The consequent loss of electrolyte-rich intestinal fluid causes hyponatraemia and hypokalaemia. A metabolic acidosis ensues from the fixed base losses into the gastrointestinal tract with the excretion of persistently acid urine. The urinary calcium excretion is low but the oxalate concentration and excretion is high, especially in patients with an intact colon. Urinary calculi of all types (urate and oxalate) are very common in patients after small bowel resection and the vast majority of patients will develop this complication during their lifetimes.

The water and salt depletion results in increased secretion of aldosterone in an attempt at maximal renal salt conservation but at the expense of increased potassium loss. This chronic hypokalaemia apart from causing muscle weakness, anorexia and cardiac arrhythmias may limit protein synthesis and impair transport and utilization of carbohydrates. In addition it may lead to the development of a renal tubular nephropathy consisting of a characteristic patchy vacuolar change in the cells of the proximal convoluted tubules. This syndrome of hypokalaemic vacuolar nephropathy can complicate other disorders associated with diarrhoea including ulcerative colitis and coeliac disease.

Metabolic bone disease

Hypocalcaemia and hypomagnesaemia are common and often associated with neuromuscular symptoms, dehydration and other electrolyte abnormalities. Osteomalacia is common but difficult to confirm without a bone biopsy. These patients have bone pain and an elevated serum alkaline phosphatase activity.

Treatment

The treatment of short gut syndrome is centred on supporting the patient during the initial stage of decompensation and through the critical stage of adaptation which may last up to 3 months. At the end of this time the stage of equilibrium is reached and the patient with residual small intestine enters the final stage of rehabilitation. In the patients with massive small bowel resection indefinite total parenteral nutrition via a permanent tunnelled silicon feeding line is the only option for survival. In these patients a programme of training with regard to the management of the intravenous feeds and the care of the feeding lines is essential so that they can eventually carry out the parenteral nutrition themselves in their own homes usually at night.

In the immediate postoperative period total parenteral nutrition is essential and the regimen must provide 40 kcal per kilogram of body weight and 300 mg of nitrogen per kilogram of body weight, in addition to electrolytes, vitamins and trace metals, usually in a 3 litre single bag system administered over a period of 12 hours. Accurate fluid balance must be maintained by daily charting of the input versus the output which should include all measured losses. H_2-receptor blockade therapy (cimetadine or ranitidine) should be administered 6 hourly by the intravenous route to suppress gastric secretion. This avoids the necessity for nasogastric intubation and suction which should only be used if ileus is prolonged. Initially nothing other than weak hypotonic electrolyte solutions are tolerated orally and only small amounts (15–30 mL/h) should be given to avoid a dry mouth.

When the patient's condition becomes stable (usually 3–6 weeks after the enterectomy) transition to an oral diet is started in those patients with an adequate length of small intestine. The feeding is started gradually, initially with isotonic carbohydrate and electrolyte solutions. Thereafter elemental diets are used. These are semisynthetic fibre-free liquid diets containing all the basic components (protein, hydrolysates, simple carbohydrates, essential lipids, vitamins). The nitrogen component is available either as free amino acids (elemental) or as peptides (polymeric). There is some evidence that the peptide-based polymeric diets lead to better nitrogen utilization than the elemental diets although this is controversial. The fats which contribute only a small amount of the caloric content of these artificial diets are necessary particularly as a supply of essential fatty acids.

The diet is administered via a nasogastric feeding tube, initially in a dilute form (1:4) and instilled by an infusion pump at a rate of 25 mL/h. The rate and concentration are gradually increased until the patient is receiving 100–120 mL of full strength diet per hour. Care must be taken that gastric dilatation does not occur as pulmonary aspiration with a fatal outcome may occur during nasogastric enteral feeding.

One of the most common early problems is diarrhoea which is often accentuated at the start of enteral feeding. The most effective drugs to control this are loperamide hydrochloride, diphenoxylate hydrochloride and codeine phosphate. In patients with an intact colon, cholestyramine can be administered to limit the diarrhoea-inducing effects of the unabsorbed bile salts. In some patients the diarrhoea is so severe that it may be life threatening and requires control using an infusion of a long-acting analogue of somatostatin.

Steatorrhoea is common in these patients and results from excess fat in the diet. Whenever possible, dietary fats should be administered as MCTs which should not require the presence of salts for their absorption into the portal venous blood. Dietary supplements of calcium, magnesium, vitamins C, D and K and iron are all necessary. In patients in whom the ileum has been resected vitamin B_{12} is administered parenterally at 3 monthly intervals on an indefinite basis.

Currently home total parenteral nutrition is the only option for the majority of patients with insufficient residual small bowel. This is costly and attended by significant complications.

Although still in its infancy, combined hepatic and small bowel transplantation offers the best prospects for management of these patients in the long term.

Remedial surgical procedures

In adults, surgery is rarely indicated in patients with short gut syndrome unless intractable diarrhoea proves resistant to all forms of medical treatment including somatostatin. Under these cases reversed (antiperistaltic) segments can be employed. Although they do delay transit they can lead to intestinal obstruction and favour the development of bacterial overgrowth. In order to avoid risks of strangulation the antiperistaltic segment should be constructed without reversal of the mesenteric pedicle (Figure 29.31). In neonates and infants, the procedure of intestinal lengthening has given good results but the procedure is difficult and should be done in expert paediatric surgical centres (Figure 29.32). Truncal vagotomy and pyloroplasty although often used in the past is not indicated as patients who develop persistent gastric acid hypersecretion can be treated using oral omeprazole on a long-term basis.

Figure 29.31 Technique of creating an antiperistaltic segment without reversal of the mesenteric pedicle.

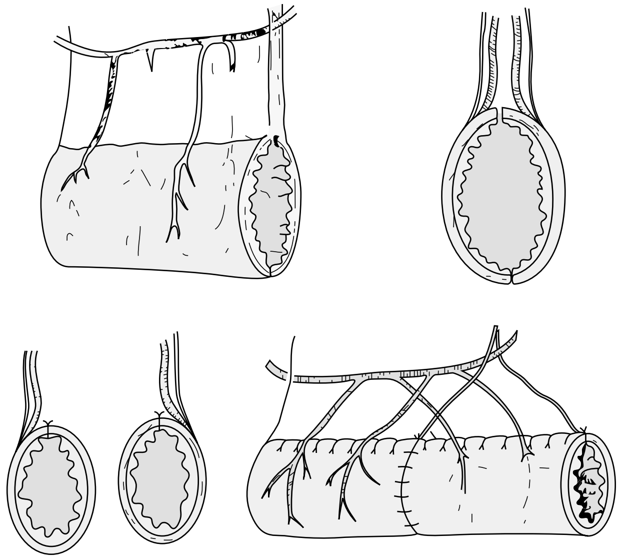

Figure 29.32 Diagrammatic representation of the intestinal lengthening operation of Bianchi. The bowel is split longitudinally into two halves, each retaining its blood supply. A tube is constructed from each half. The two tubes are then joined together.

Coeliac disease (gluten-sensitive enteropathy)

Coeliac disease is the most common and important cause of malabsorption in Western societies, but its prevalence varies considerably. In the UK, the overall prevalence in the population is about 1 in 300. An increased prevalence is also found in individuals with Irish, Punjabi and other South Asian ethnic origin. Coeliac disease is the result of an intestinal allergic reaction to gluten, a dietary protein found mainly in wheat and to a lesser extent in rye and barley. Coeliac disease is an inherited disease of the intestinal immune system and affects both sexes. It is often missed early on in life, being misdiagnosed with other intestinal disorders, such as irritable bowel syndrome and Crohn's disease. Thus the majority of patients are usually diagnosed in adult life. Untreated coeliac disease is associated with long-term health risks, e.g. miscarriages, osteoporosis, anaemia and gastrointestinal malignancy.

Pathology

Coeliac disease is characterized by a mucosa with shortened villi and lengthened crypts in the upper small intestine. The severity of the disease increases with the extent of involvement of small intestine but it is relatively unusual for the whole of the ileum to be involved. The histological hallmark of coeliac disease is subtotal villous atrophy but the mucosa remains of normal thickness due to the crypt hyperplasia.

Aetiology

Coeliac disease is regarded as a multigenetic disorder, associated with HLA types HLA-DQ2 (90%) or HLA-DQ8, plus other genetic or environmental factors. There is a familial tendency with 10–15% of first-degree relatives being affected. Antenatal HLA testing is used to provide information to parents of a coeliac disease child desiring to know the risk of the disease in a further child. The disease is also commoner in patients with type 1 diabetes mellitus (2–8%), Down syndrome, sarcoidosis, infertility (both sexes), patients with IgA antibody deficiency and certain autoimmune disorders (thyroid disease, rheumatoid arthritis, chronic active hepatitis, Addison disease and Sjörgen syndrome).

Clinical features

The disease may present at any time of life from the first few months to old age. Coeliac disease presentation in childhood is uncommon in the UK with only 9% being diagnosed in this age group. Babies and young children present after weaning (9 months to 3 years) with malabsorption and diarrhoea (frequent pale stools) but sometimes paradoxically with constipation, refusal to feed, weight loss/failure to thrive, vomiting, anorexia and irritability. On examination, the abdomen is protruberant with eversion of the umbilicus.

Older children and adults may present with anaemia (folate or iron deficiency), abdominal discomfort, arthralgia, fatigue and malaise, diarrhoea, steatorrhoea and malabsorption. On examination, mouth ulcers and angular stomatitis are common and are associated with deficiencies of folate (85%), vitamin D (up to 30%), vitamin K (10%) and vitamin B_{12}. Some adult coeliac disease patients present with infertility (both sexes) and females with repeated miscarriages.

The classical manifestations of coeliac disease include malabsorption, chronic diarrhoea, anaemia, rickets, failure to grow, abdominal bloating, offensive bulky stools, dermatitis herpetiformis (blistering itchy rash on the back, elbow and scalp) and mouth ulcers. In adults, coeliac disease often presents with non-specific symptoms, e.g. fatigue, mouth ulcers, skin rashes, vague abdominal pains, intermittent diarrhoea and chronic anaemia. The vast majority of patients who develop dermatitis herpetiformis will have coeliac disease.

Diagnosis

Antibody screening tests

These measure antibodies to gluten or gliadin and endomysial antibodies (EMAs) to the damaged bowel wall and are used as the initial screening test. The antigliadin antibodies, which disappear on a gluten-free diet, are no longer recommended as they are less specific and can be positive in other gastrointestinal conditions, such as Crohn's disease.

Assays for IgA antitissue transglutaminase antibody (tTGA), which is the autoantigen of EMA, are nowadays the preferred investigation. EMAs are used if the tTGA test is not available or equivocal. Both tests are highly specific and sensitive for untreated coeliac disease, provided the patient is still on a gluten diet. Even so in patients with positive antibody tests the disease needs to be confirmed by an intestinal biopsy performed with the patient on a normal (wheat) diet. False-negative results occur in patients with selective IgA deficiency (0.4% of the general population). The current recommendation is for the use of IgG tTGA and/or IgG EMA serological tests in patients with confirmed IgA deficiency. Antibodies frequently become undetectable after 6–12 months on a gluten-free diet and can be used to monitor the disease.

Serological testing is recommended in patients with irritable bowel syndrome and children with type 1 diabetes. The National Institute for Health and Clinical Excellence also recommends serological testing in patients with Addison disease, amenorrhoea, aphthous stomatitis, autoimmune liver disease, autoimmune myocarditis, chronic thrombocytopenic purpura, dental enamel defects, depression, Down syndrome, epilepsy, lymphoma, metabolic bone disease (rickets or osteomalacia), persistent or unexplained constipation, polyneuropathy, recurrent miscarriage, sarcoidosis, Sjögren syndrome, Turner syndrome, unexplained alopecia and unexplained subfertility.

Other tests

A small bowel follow-through shows an abnormal appearance in 90% of patients although the appearances are non-specific. The normal fine feathery appearance of the mucosa is no longer seen but is replaced by a coarse mucosal pattern with broad bars. As the disease becomes more severe the small bowel may appear as a featureless tube. Changes are mainly seen in the jejunum but distal spread is seen in more severe disease.

The most important diagnostic test is jejunal biopsy which can be achieved either at upper gastrointestinal endoscopy or using a suction (Crosby) capsule. At endoscopy it is common to see loss of the folds of Kerckring in the descending duodenum and this should alert the endoscopist to the possibility of coeliac disease. In any case, the diagnosis of coeliac disease is confirmed when biopsy shows villous atrophy while the patient is on a gluten diet, followed by full clinical remission with a gluten-free diet when the tTGAs or EMAs gradually disappear. Further biopsy following gluten challenge may be needed in borderline cases.

Other investigations which should be done include full blood count and blood film for Howell–Jolly bodies (splenic atrophy), liver function tests and small bowel contrast studies to exclude other causes of malabsorption/diarrhoea or lymphoma.

Complications

To a certain extent, although the gut is the main organ of gluten sensitivity, the condition can be systemic. The non-bowel-related complications include dermatitis herpetiformis and neurological dysfunction leading particularly to cerebellar ataxia often with a peripheral neuropathy. The main complications of coeliac disease related to the intestinal disease are nutritional deficiencies leading to iron-deficiency anaemia, polyvitamin deficiencies and osteoporosis with fractures (50%). The patients are also at an increased risk of mouth, throat, oesophageal and small bowel cancer. Coeliac disease is also associated with an increased risk of developing some types of lymphoma, the commonest being enteropathy-type T-cell lymphoma but these patients have an increased risk of other types of NHLs. Overall the incidence of malignancy in adult coeliac disease is in the region of 10%.

Treatment

The only effective treatment of coeliac disease is strict lifelong complete avoidance of gluten found in cereals such as wheat, rye and barley (many tolerate oats). It is completely safe for coeliac disease patients to eat maize, corn or rice. With the increased potential for developing osteoporosis, coeliac disease patients should be closely monitored and all menopausal women and men over 55 years of age who suffer with coeliac disease should have bone density (DEXA) scanning.

The gluten-free diet rapidly induces clinical improvement, which is mirrored by restoration of the villous architecture of the mucosa. The diet consists of no wheat, barley, rye, or any food containing them. Although moderate quantities of oats are allowed, the British Society of Gastroenterology guidelines suggest oats be excluded at least for the first year while patients get accustomed to a gluten-free diet before oats are cautiously introduced. A gluten-free diet should be life-long, as relaxation of diet precipitates a relapse of symptoms and increases the incidence of complications. The diet should be supplemented by folic acid, iron, calcium and vitamin D as necessary. Serial tTGAs or EMAs are used to monitor response to diet. tTGA is the autoantigen of EMA.

Vascular abnormalities of the gut

These constitute a heterogeneous group of conditions which share a related pathology consisting of abnormal lesions of the gut alone or with similar lesions in other organs including the skin. Not all lesions are symptomatic, but when they are any of the gut lesions present most usually with obscure recurrent gastrointestinal bleeding and less commonly with life-threatening haemorrhage. In the vast majority of cases, treatment is with endoscopic therapy, less commonly with interventional angiography. Surgery has a limited role in the treatment nowadays, being reserved for major bleeding which is not controlled by other therapies. The lesions which are malformations rather than neoplasms include angiodysplasia, phlebectasia, telangiectasia and haemangiomas.

Angiodysplasia

The terms angiodysplasia, arteriovenous malformation, angioectasia, and vascular ectasia are often used synonymously. The confusion is added to by the fact that while some authors use angioectasia as a generic term, others reserve it for colonic lesions.

Angiodysplasias are lesions which occupy the mucosa and submucosa of the gastrointestinal tract and consist of a cluster of arteriolar, venular and capillary vessels. Although this condition can occur in the small bowel it is most commonly seen in the right side of the colon. Angiodysplasia may cause gastrointestinal bleeding usually of the recurrent occult type, but rarely the bleeding may be overt and severe, causing life-threatening hypovolaemia. The aetiology is uncertain but theories include chronic mucosal ischaemia secondary to arteriovenous shunting, decreased perfusion pressure and lowered oxygen tension in the terminal branches of the SMA and chronic intermittent obstruction of the submucosal veins.

Pathology and aetiology

Gastrointestinal angiodysplasia is usually found in the elderly (≥60 years) with an estimated incidence of 0.8%, but may rarely affect younger patients. However, the prevalence of angiodysplasia is increased in patients with advanced renal disease, aortic valve stenosis and in von Willebrand's disease. Approximately half of affected patients have more than one lesion. The majority of angiodysplasias occur in the colorectal region, mainly in the right colon (70–80%), the commonest site being the caecum. However, lesions in the small bowel and gastroduodenal region may occur in their own right, or as synchronous lesions in association with colonic angiodysplasias.

Angiodysplasias are composed of ectatic, thin-walled vessels lined by endothelium alone or with small amounts of smooth muscle intimately associated with dilated, tortuous submucosal veins. Large lesions are associated with enlarged feeding arterioles and arteriovenous fistulas. The pathogenesis of angiodysplasia remains unclear. The most favoured theory is intermittent, low-grade obstruction of submucosal veins at the level of the muscularis propria. In time this venous obstruction results in dilatation and tortuosity of the related submucosal venules and capillaries. This hypothesis is consistent with the high incidence of angiodysplasia in the right colon where intraluminal and wall tension is highest. Another hypothesis postulates increased expression of angiogenic factors as the cause. A possible mechanism by which aortic stenosis may lead to the development of angiodysplasia is through the development of an acquired form of von Willebrand disease due to mechanical disruption of von Willebrand multimers from the turbulent blood flow passing through the narrowed aortic valve in association with the thrombocytopenia which characterizes this disease.

Angiodysplasia of the small intestine presents with recurrent obscure bleeding in patients with negative upper gastrointestinal endoscopy and colonoscopy (5%). These cases are nowadays diagnosed with small bowel endoscopy or DBe which can also be used for treatment. Angiodysplasia of the stomach or duodenum is the least common and is responsible for 5% of gastrointestinal bleeding episodes, which may be occult, presenting with iron-deficiency anaemia, or overt, causing haematemesis.

Clinical manifestations and diagnosis

The usual presentation of angiodysplasia is with recurrent/chronic obscure gastrointestinal bleeding, which is usually minor but may rarely be severe in patients with large arteriolized lesions and accompanied by life-threatening hypovolaemia. Angiodysplasia may also be discovered incidentally during an endoscopy for unrelated reasons.

In patients with end-stage renal disease, angiodysplasia is the cause of upper and lower gastrointestinal bleeding recurrent episodes in 30%. In these patients angiodysplastic lesions are often multiple and may occur anywhere in the gut. The increased risk of bleeding in uraemic patients is thought to be platelet dysfunction induced by the end-stage renal disease. The higher incidence of bleeding from angiodysplasia in patients with von Willebrand disease is related to the underlying coagulopathy. In patients with aortic stenosis the recurrent bleeding episodes are reduced markedly in those treated with aortic valve replacement.

Angiodysplasia is usually diagnosed by endoscopy (upper gastrointestinal, colonoscopy, CE, single/double balloon enteroscopy) performed in patients with episodes of gastrointestinal bleeding. Initially all patients have upper gastrointestinal endoscopy and colonoscopy, with other endoscopy tests being performed if the cause of the gastrointestinal bleeding remains obscure. Endoscopically, angiodysplasias have a characteristic appearance of small (5–10 mm), flat, cherry red lesions with a mesh of ectatic blood capillaries radiating from a central vessel. Opioid antagonist (naloxone) administration is reported to increase the detection rate of colonic angiodysplasias. CT or magnetic resonance angiography are also used for the diagnosis of angiodysplasia, although their sensitivity and specificity are lower than that of colonoscopy. In angiodysplasia the typical angiographic finding consists of a tortuous feeding artery and dilated veins with an intervening cluster of fine vessels. When there is active bleeding angiography may demonstrate extravasation of contrast into the small bowel lumen and scanning using labelled autologous red cells may be of value.

Treatment

The current opinion is that angiodysplasias discovered incidentally during colonoscopy do not require active treatment as the risk of subsequent bleeding is low. In contrast, all patients with occult bleeding require treatment as the risk of rebleeding is high especially in patients with multiple lesions and in patients with a bleeding tendency from any cause. All patients with overt bleeding require immediate treatment.

A variety of endoscopic treatments can be used. Argon plasma coagulation is the most common modality as it is safe, effective and cheap. Bipolar electrocoagulation and heater probe coagulation are also effective in the treatment of angiodysplasia, although perforation with heater probe coagulation is a recognized risk. Monopolar electrocoagulation is no longer used because of this risk. Other techniques for arrest of bleeding angiodysplasias include mechanical haemostatic methods with endoscopic clips and band ligation. These are favoured in patients on anticoagulants and/or antiplatelet agents, and in patients with coagulation defects. Angiography to localize the site of active bleeding followed by its embolization-is reserved for patients with life threatening bleeding who are not surgical candidates. Surgery has a limited place and is only considered in patients with large transfusion requirements or life-threatening haemorrhage from a clearly identified site. For lesions of the small bowel causing significant haemorrhage, resection of the affected segment of small bowel is carried out. Ideally, if mesenteric angiography has been carried out prior to surgery, the radiologist should leave a superselective catheter in a mesenteric vessel as close to the lesion as possible. At surgery, the surgeon can then inject some dye (methylene blue) into the catheter and this will highlight the segment of small bowel to be resected.

Phlebectasia

Phlebectasias are rare benign vascular anomalies of the gastrointestinal tract, with only a few reported cases to date. These lesions are usually asymptomatic and are usually discovered at postmortem or incidentally during surgery, but, occasionally, they present with mild to massive gastrointestinal haemorrhage. Essentially they consist of a meshwork of dilated veins having a normal endothelial lining and situated in the submucosal layer of the intestine with a thin overlying mucosa. Endoscopically, they appear as multiple, dark bluish red nodules, less than 1.0 cm in diameter, which blanch on pressure. The exact cause of phlebectasia is not known and suggested theories include a congenital abnormality of the endothelial lining of submucosal veins and age-related loss of connective tissue support surrounding the submucosal veins.

Phlebectasia, which may be multiple, can occur in any segment of the gastrointestinal tract, including the small intestine but the jejunum is one of the commonly reported sites. When discovered, phlebectasia must be distinguished from varices as the endoscopic appearances are identical, distinction being based on the absence of cirrhosis and other manifestations of portal hypertension. Histologically, they consist of dilated veins lined by a single layer of endothelial cells and irregular bundles of smooth muscle in the tunica media without internal or external elastic lamina. Detection can be difficult in symptomatic cases but the same investigations described in the section on angiodysplasia are used to establish the diagnosis. Multiple phlebectasia of the jejunum, associated with similar lesions of the oral mucosa, tongue ('caviar spots') and scrotum (Fordyce lesion) have been reported.

Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu disease)

Hereditary haemorrhagic telangiectasia (HHT) is a rare inherited disorder which leads to multiple telangiectasias of the lip, mouth, nasopharynx and gut and other internal organs. The lesions consist of arteriolar dilations and arteriovenous malformations due to a congenital weakness of the arterial muscle and absence of elastin in the medial coat. The prevalence of HHT is estimated at one in 5000–8000 individuals. The coagulation is normal in affected patients. HHT, also known as Osler–Rendu–Weber disease, is characterized by a tendency for bleeding, especially recurrent epistaxis, cutaneous telangiectasia and bleeding in internal organs including the small intestine.

Pathology

HHT is an autosomal dominant vascular dysplasia leading to telangiectasias and arteriovenous malformations of skin, mucous membranes and internal organs. Two main types of HHT are recognized: (1) the most frequent (HHT1) is due to mutations of the *END* gene coding for endoglin on the long arm of chromosome 9 at 9q34.1 (MIM.187300); and (2) HHT2 due to mutations at 12q11-q14 (MIM.600376) coding for the *ACVRL1* gene. There is also a variant in which HHT occurs in association with juvenile polyposis.

Clinical features

The diagnostic criteria for HHT include (1) spontaneous recurrent nosebleeds, (2) multiple telangiectasias on skin and mucous membranes, (3) involvement of internal organs and (4) an affected parent, sibling or child. The first sign of HHT usually does not occur until puberty or adulthood with the average age of the first nosebleed occurring at 12 years. Recurrent nosebleeds are seen in 50–80% of patients with HHT. Bleeding episodes vary from daily to weekly and monthly nosebleeds depending on severity of the disease – roughly one-third mild, one-third moderate and one-third severe. Telangiectasia of the skin and mucous membranes may occur anywhere but predominate on the upper half of the body including the face, inside the mouth and nostrils, lips, ears, conjunctiva of the eyes, forearms, hands and fingers. Telangiectasia and arteriovenous malformations in other parts of the body affect 95% of patients but these usually appear in adult life (between 20 and 40 years). Lesions can be found anywhere in the Gastrointestinal tract (oesophagus, stomach and small and large bowel). Gastrointestinal bleeding occurs in about 25% of patients with HHT and the risk increases in patients older than 50 years. Other organs which may be involved with internal bleeding include the lungs (30%), the brain and spinal cord.

Treatment

Mild cases usually require no treatment. HHT requires treatment if it causes significant problems, such as severe and/or frequent nosebleeds, or if there is a high risk of causing other problems. Nosebleeds are treated with laser coagulation therapy or surgically with nasal septal dermoplasty or complete nasal closure (Young's procedure). Gastrointestinal bleeding causing anaemia is treated with iron replacement therapy. If this is ineffective then blood transfusion and endoscopic coagulation are needed.

Gastrointestinal haemangiomas

Gastrointestinal haemangiomas are uncommon benign vascular malformations that may occur anywhere in the gastrointestinal tract as single or multiple lesions. They are commonest in the small intestine accounting for 10% of small bowel lesions, followed by the colon. Multiple lesions are often associated with haemangiomas in other organs (liver and skin) and may also be a feature of other disorders, e.g. *Osler–Weber–Rendu disease*, *Maffucci syndrome*, *Klippel–Trénaunay syndrome*, or the congenital *blue rubber bleb naevus syndrome*. They present most commonly with gastrointestinal bleeding, which may be slow and occult or overt with life-threatening hypovolaemia.

Pathology

Macroscopically gastrointestinal haemangiomas usually form pedunculated polypoid masses and less commonly diffuse submucosal infiltrating lesions. The common sites in descending order of reported cases are the small intestine (40%), colon (30%) and gastro-oesophageal (10%). Very rarely, they are diffuse throughout the gastrointestinal tract and may involve other organs (gastrointestinal haemangiomatosis). Haemangiomas appear endoscopically as red to bluish lesions with a soft compressible consistency, unless they contain areas of thrombosis/calcification (phleboliths). Histologically, they are classified in accordance with the nature of their major vascular components into three types: capillary, cavernous or mixed. Capillary haemangiomas consist of a mass of small capillaries and thin-walled blood-filled spaces, whereas the cavernous types contain large sinuses lined by single or multiple layers of endothelial cells. Cavernous haemangiomas may infiltrate large segments of the small intestine and adjacent mesentery. Both types may exhibit areas of thrombosis with calcification and hyalinization. When haemangiomas originate from the mesentery, large segments of the small bowel may be involved. Focal calcification, thrombi and hyalinization represent degenerative changes.

Clinical features

Irrespective of site of origin, gastrointestinal bleeding is the most common clinical presentation. The bleeding may be slow and insidious or massive and life threatening. Cases have been reported when extensive cavernous haemangiomas have been complicated with diffuse intravascular coagulation with widespread massive bleeding due to the coagulopathy. Patients with small bowel lesions may also present with abdominal pain, mechanical bowel obstruction due to the formation of intramural haematoma, intussusception or perforation. The differential diagnosis of small bowel haemangiomas includes other benign and malignant small intestine tumours as well as metastatic disease. Other conditions, e.g. lymphoma, metastatic disease, primary peritoneal malignancies and inflammatory pseudotumour, should be considered in the differential diagnosis for lesions that infiltrate the mesentery and small intestine.

In patients with extensive involvement, small bowel contrast radiology may show displacement of the bowel, irregularities of the mucosal folds or a polypoid intraluminal mass. CT can identify a large mass contiguous with the small intestine in these patients, but small lesions may be radiographically occult and difficult to detect before surgery. Abdominal plain radiographs may show phleboliths. Occasionally, when haemangiomas originate from the mesentery, large segments of the small intestine may be identified as a large mass contiguous with the small intestine on CT. In contrast, small lesions may be missed and these are notoriously difficult to detect by radiological tests before surgery. However, except in the emergency situation, these investigations have been largely replaced by CE and balloon endoscopy (single and double). CE is usually done first as it is far less invasive. However balloon endoscopy gives a more precise assessment of the extent of the disease and in selected cases (e.g. small solitary polypoid lesions) may enable endoscopic treatment.

In the colon the most common site is the rectosigmoid followed by the right colon and caecum. Most patients with rectosigmoid haemangiomas are young men. Irrespective of colonic segment involved, all patients present with rectal bleeding. The presence of clusters of phleboliths with atypical distribution within the pelvis is common in colorectal haemangiomas and is a useful sign in young patients. Haemangiomas of the rectosigmoid may widen the retrorectal space on CT caused by the transmural thickening of the involved segment. MRI of rectosigmoid haemangiomas shows focal thickening of the colonic wall with high signal intensity on T_2 weighted images in both the lesion and perirectal fat.

Oesophageal haemangiomas constitute 3.0% of all benign oesophageal tumours. They may occur at any level in the oesophagus and often present with dysphagia, but may also produce haematemesis and melaena. Diagnosis is established by barium swallow which outlines a well-defined lobulated or a pedunculated intraluminal mass and upper gastrointestinal endoscopy. When discovered at endoscopy, biopsy must never be attempted because of the real risk of catastrophic haemorrhage. The differential diagnosis.

Treatment

Once diagnosed all gastrointestinal haemangiomas require treatment in view of their propensity to bleed in addition to other complications. It is best to consider treatment in the elective and emergency situations.

Elective treatment

With the exception of small polypoid lesions which can be treated endoscopically by balloon endoscopy (laser fulguration, heater probes, etc.), provided local expertise is available, the vast majority of small bowel lesions require segmental resection of the affected small intestine. This is usually carried out by open surgery but, provided the lesion is accurately localized, there is no reason why this cannot be done by the laparoscopic approach. Indeed there have been several reported series of the value and benefit of laparoscopy both in the diagnosis and accurate localization of small bowel haemangiomas and in the surgical treatment by laparoscopic segmental resection. In most of the reported series, the enteroenteric anastomosis has been done extracorporeally though the small incision used to extract the specimen, but internal restoration of continuity by stapling or intracorporeal suturing is a valid alternative.

Emergency treatment

Patients presenting with acute massive gastrointestinal haemorrhage require replacement of the hypovolaemia and stabilization with blood/colloid transfusions. This is followed, soon after, because of the real risk of recurrence of bleeding, with emergency radiological intervention requiring superelective cannulation of the feeding vessels to locate and embolize the lesion. Often a blue dye is also injected together with the contrast medium. The reason for this is that should the embolization fail and an emergency laparotomy is needed, the surgeon can more easily locate the involved small bowel segment. Less commonly, emergency laparotomy is need for haemangiomas causing perforation or small bowel obstruction from intussusception or the formation of intramural haematoma. Again resection with end-to-end anastomosis is carried out.

Gastrointestinal haemangiomatosis

This is a complex vascular malformation that occurs primarily in infancy and childhood. Most patients present with gastrointestinal bleeding. In others, the presentation is with intussusception, small bowel obstruction, perforation or protein-losing enteropathy/malabsorption. Gastrointestinal haemangiomatosis may be associated with blue rubber bleb naevus syndrome, Klippel–Trénaunay–Weber syndrome, Maffucci syndrome, diffuse neonatal haemangiomatosis and Proteus syndrome. Pathologically, haemangiomatosis is characterized by diffuse infiltration of the intestinal wall, the mesentery, and, occasionally, the retroperitoneum. Solid organs in the abdomen may also be involved. The radiographic findings include the presence of phleboliths (plain abdominal films) and mural thickening on CT.

The vermiform appendix and Meckel's diverticulum

Vermiform appendix

Anatomy

The appendix appears during the fifth month of gestation. Initially several lymphoid follicles are scattered throughout the developing organ. These follicles increase with growth up to 8–20 years of age. The vermiform appendix is a narrow (around 5 mm) diverticulum of highly variable length (5–15 cm). The base of the appendix is attached to the posteromedial surface of the caecum approximately 3 cm inferolateral to the junction of the ileum and caecum. Its blood supply, which originates from the ileocolic artery, reaches it via a small extension of the mesentery of the small bowel, which passes posterior to the terminal ileum. The appendix is highly variable in position. Often (65%) it lies posterior to the caecum (retrocaecal) but it may also extend into the iliac fossa and lesser pelvis (30%) and lie close to the ovary, fallopian tube and ureter. As with the small bowel, the appendix is covered with peritoneum and has an external layer of longitudinal muscle and an internal layer of circular muscle. At the base of the appendix the longitudinal muscle is continuous with the three taeniae of the caecum and the colon. In the submucosal layer there are lymph follicles which are separated by crypts of the columnar epithelial lining that contains many goblet cells. When the submucosal layer becomes swollen it can readily block the lumen of the appendix.

Aetiology and epidemiology of appendicitis

Appendicitis is caused by obstruction of its lumen, most commonly by lymphoid hyperplasia (more common during childhood and in young adults) secondary to various inflammatory and infectious conditions, e.g. gastroenteritis, respiratory infections, measles, infectious mononucleosis and inflammatory bowel disease. The other common cause of appendiceal obstruction leading to appendicitis is faecalith impaction (more common in elderly patients). Rare causes include parasites, foreign bodies and neoplasms. Obstruction is less commonly due to bacterial infections.

The high incidence of acute appendicitis in the West and its relative rarity in Africa suggest a protective effect of a high-fibre diet. The high-fibre diet decreases bowel transit time and is thought to minimize the formation of faecaliths. There is also evidence that appendicitis is commoner in urban society than in rural districts, and this may be attributed to a high incidence of enteric infections related to crowded living conditions. Domestic and food hygiene have improved dramatically over the past 40 years and this has coincided with a significant fall in the incidence of appendicitis. There is also epidemiological evidence indicating that the consumption of green vegetables and tomatoes may be protective against appendicitis, whereas potato consumption appears to be related to the disease. In elderly patients there is some evidence that chronic intake of non-steroidal anti-inflammatory drugs may increase the risk.

Acute appendicitis

Pathology

The obstruction causes an elevated intraluminal pressure from increased secretion of fluids and mucus by the mucosa with stasis of the contents and proliferation of intestinal bacteria which recruit polymorphonuclear leucocytes forming pus, thereby inducing a further rise in the intraluminal pressure. This ultimately leads to venous outflow obstruction, ischaemia, loss of epithelial integrity and bacterial invasion of the appendiceal wall. As the pathology progresses thrombosis of the appendicular artery and veins occurs with gangrene and perforation of the appendix forming a periappendicular abscess or local/generalized peritonitis.

The presence of gangrene or perforation seems to be associated with the presence of faecaliths, which are radio-opaque intraluminal laminated appendiceal calculi. Approximately 50% of cases of gangrenous or perforated appendicitis are associated with a faecalith in contrast with uncomplicated appendicitis in which a faecalith is rarely present. The rate of perforation varies from 16% to 40%, with a higher frequency occurring in younger age groups (40–57%) and in patients older than 50 years (55–70%), in whom misdiagnosis and delayed diagnosis are common.

Clinical features

Appendicitis is one of the more common surgical emergencies and is the commonest cause of abdominal pain requiring hospital admission. In this context, acute abdominal pain is defined as previously undiagnosed pain of <72 hours' duration. The current annual incidence of acute appendicitis is one in 1000 individuals. There is a slight male preponderance (3:2) in teenagers and young adults. In adults, the incidence of appendicitis is approximately 1.4 times higher in males. The incidence of appendicitis peaks in the late teen years, and gradually declines thereafter. In the paediatric age group the mean age at presentation is 6–10 years. This is thought to result from the higher prevalence of lymphoid hyperplasia.

History

Owing to the embryological origin of the appendix as a midline structure the majority of patients with acute appendicitis first notice a pain which starts in the region of the umbilicus. This pain may be a dull ache or it may be colicky pain presumably owing to obstruction of the appendiceal lumen. After a variable period of time the pain shifts to the right lower quadrant of the abdomen owing to the inflamed appendix irritating the parietal peritoneum. It must be stressed, however, that approximately 30% of patients do not experience this shift of pain and their symptoms start with discomfort in the right lower quadrant. Patients will usually report that movement, particularly coughing or laughing, leads to sharp exacerbations of the pain. Nausea and vomiting are common and anorexia is almost inevitable. It is important to appreciate that about 20% of patients will also have diarrhoea, particularly when the appendix lies in the pelvis, and this may lead to a mistaken diagnosis of gastroenteritis. Symptoms may be altered by other location of the inflamed appendix: flank and back pain in retrocaecal appendicitis, urinary symptoms with pelvic location.

In taking the history it is important to ask questions which might alert one to possible alternative diagnoses. Particularly in children it is important to ask about a sore throat or flu-like symptoms as these often accompany mesenteric adenitis. The patient should be asked about dysuria, frequency and cloudy or strong smelling urine, as urinary tract infection can often lead to lower abdominal pain. In women, a menstrual history is essential. A missed period may point to an ectopic pregnancy. Pain at mid-cycle may indicate that the pain is due to ovulation (Mittelschmerz) and vaginal discharge may indicate pelvic inflammatory disease.

Examination

The first part of the examination should consist of general inspection of the patient's wellbeing with measurement of their pulse and temperature. Patients with appendicitis may well have a normal pulse rate and temperature, but a sustained tachycardia is highly significant in the presence of abdominal pain and tenderness and should always be taken seriously. Although the temperature may be normal, most patients with appendicitis have low-grade pyrexia. A very high temperature (above 39°C) indicates probable abscess formation or some other diagnosis such as a viral illness.

The next stage is to observe the patient's abdomen and to look for movement with respiration. It is then useful to ask the patient to cough while watching their facial expression. If coughing produces obvious pain the patient should be asked to indicate the site of maximum pain. If this lies in the right iliac fossa this will indicate localized peritonitis in this area and is highly suggestive of appendicitis. The tongue, mouth and throat should be examined as a furred tongue and fetor oris will be present in about 50% of patients, particularly those with a delayed diagnosis. The tonsils should also be inspected particularly in children, as tonsillitis may be associated with mesenteric adenitis.

Attention should then be turned to palpation of the abdomen. The first point to establish is the site of maximal tenderness. In the majority of patients this is at or close to 'McBurney's point' which is situated at the junction between the upper two-thirds and lower one-third of a straight line joining the umbilicus and the anterior superior iliac spine. It must be stressed, however, that in patients with inflammation in a retrocaecal appendix the pain may be considerably higher and more lateral than this, and in pelvic appendicitis the pain may be lower and almost midline. Indeed, with a low pelvic appendix tenderness may be only detectable by rectal examination. The abdomen should then be assessed for guarding or the involuntary contraction of the abdominal wall muscles over the area of inflamed peritoneum. Right lower quadrant guarding is found in about 90% of patients with acute appendicitis and if the appendix has perforated leading to generalized peritonitis the area of guarding may extend beyond the right lower quadrant. Rebound tenderness is another useful sign. This may be elicited by pressing gently on the right lower quadrant of the abdomen and then suddenly releasing the hand and watching the patient's face for signs of discomfort. Another approach is to use percussion which, in the presence of peritoneal irritation, will elicit the same response and is kinder.

When the amount of tenderness permits, careful palpation of the right iliac fossa for a mass should be carried out. This may indicate the presence of an appendiceal abscess or an appendix mass (phlegmon) created by omentum wrapped around the inflamed appendix. Of course, it may also indicate some other pathology such as a caecal carcinoma which is mimicking appendicitis in its presentation.

After careful examination of the abdomen, attention should be turned in the male to the testes as both acute torsion and orchitis may present initially with right lower quadrant pain. The hernial orifices should also be carefully examined for strangulated inguinal or femoral hernias and it should never be forgotten that acute appendicitis can occasionally occur in an appendix lying within a hernial sac.

Rectal examination can be extremely helpful in the clinical assessment of suspected appendicitis but in a patient with clear-cut symptoms and signs it is unnecessary. However, particularly in a patient with diarrhoea and abdominal pain who does not have convincing abdominal signs, a rectal examination should always be carried out. The examining finger should be pressed on to the pelvic peritoneum first to the left and then to the right. When there is a pelvic appendicitis there will be more discomfort felt on the right. In female patients, the surgeon should then take opportunity of moving the cervix through the rectal wall as pain associated with this manoeuvre is highly indicative of pelvic inflammatory disease.

Diagnosis

The diagnosis of acute appendicitis is made largely on clinical grounds. The problem is that the diagnosis is correct in only 50% and up to 20% of appendicectomy specimens are normal especially in females. A systemic review of published series identified the following useful predictors of appendicitis in patients with abdominal pain: raised inflammatory markers, clinical signs of peritoneal irritation, migration of abdominal pain. However, certain investigations which may be of value in problematic cases include:

- elevated white cell count and C-reactive protein
- a plain abdominal radiograph
- ultrasound and CT scanning
- pregnancy test in adult females
- laparoscopy
- urinalysis.

The majority of patients with acute appendicitis will have a polymorphonuclear leucocytosis and a white cell count of more than 14×10^9/L is suggestive of appendicitis. However, it must be remembered that various other causes of abdominal pain result in an increased white cell count and around 25% of patients with appendicitis have a normal preoperative white cell count. In patients in whom the diagnosis of acute appendicitis is doubtful and in whom a period of observation is felt to be appropriate, it is worthwhile repeating the white cell count. A falling white cell count will strongly support the diagnosis of non-specific abdominal pain.

In a patient with clear-cut symptoms and signs of acute appendicitis a plain abdominal radiograph is of little or no diagnostic value. However, it is clearly indicated if there is some clinical suspicion of intestinal obstruction or ureteric colic. An erect chest radiograph should always be requested when there is a suspicion of a perforated viscus. A urinalysis should always be carried out to exclude the possibility of urinary tract infection, bearing in mind that about 20% of patients with appendicitis will have sterile proteinuria and pyuria.

Ultrasound and CT scanning

Ultrasound examination of the pelvis is particularly useful in female patients when a differential diagnosis of gynaecological pathology such as a twisted ovarian cyst is being entertained. It may also be useful in distinguishing between an appendix mass and an abscess. In addition to this there have been some reports indicating that ultrasound can be used to make the diagnosis of appendicitis with a high level of sensitivity and specificity. This has not become routine however owing to the fact that a high level of expertise is required. Such expertise is not routinely available for emergency situations in most institutions. CT scanning may occasionally be useful in establishing the diagnosis where a right lower quadrant mass is present. However, it does not have a place in the routine diagnosis of acute appendicitis.

Laparoscopy

Laparoscopy has an established role in the diagnosis of acute appendicitis when the clinical diagnosis is uncertain. It is particularly of value in women of child-bearing age where there are a number of different causes of right lower quadrant pain and tenderness. Several studies now testify to the reduction in the negative appendicectomy rate in such patients. Use of laparoscopy in males and in children is less well established, but whenever there is a diagnostic problem and the surgeon is unhappy about prolonged observation then laparoscopy is appropriate in any patient who has not had previous extensive abdominal surgery. During the procedure a probe should always be used in order to manipulate the caecum so that the appendix can be fully visualized.

Laparoscopy is greatly superior to a right lower quadrant gridiron incision for visualizing the abdominal and pelvic organ. For this reason it is particularly useful in planning incisions both for acute appendicitis and for other unsuspected intra-abdominal pathology. Laparoscopy can also be used to carry out appendicectomy (see section on treatment).

Complications

Complications of acute appendicitis are secondary to gangrenous or perforated appendicitis and can therefore be avoided by prompt recognition of the condition and appropriate treatment. These are:

- appendix abscess
- appendix mass
- wound infection
- generalized peritonitis, particularly in the very young or elderly
- intraperitoneal abscess formation, either subphrenic or multiple small intraloop abscesses
- faecal fistula usually following draining of an abscess
- recurrent intestinal obstruction due to the formation of adhesions
- portal pyaemia
- sterility in women of child-bearing age; there is some debate as to whether perforation of the appendix increases the rate of infertility but recent studies indicated that it is probably not a major except for patients with perforation and peritonitis leading to obstruction of fallopian tubes from adhesions
- overwhelming sepsis and death.

Treatment

In cases of doubt regarding the diagnosis, a period of 'active observation' is advisable. Reports suggest that this approach reduces the negative appendicectomy rate without increasing the risk of perforation. Intravenous fluids and analgesia should be given. Opiate analgesia should be administered as it does not mask the signs of peritonism. Antibiotics should be withheld until the decision to operate has been made.

The mainstay of treatment in acute appendicitis is early appendicectomy. This is normally done through a small skin crease incision in the right iliac fossa, which involves splitting the underlying abdominal muscles rather than cutting them. After removal of the appendix, the appendiceal stump is traditionally buried into the caecum but there have been trials to show that this manoeuvre is unnecessary. If the appendicitis is diagnosed at the time of a laparoscopy it is possible to carry out a laparoscopic appendicectomy if the surgeon has the necessary expertise. There have now been a number of randomized trials comparing conventional appendicectomy with laparoscopic appendicectomy. These have shown similar outcome except for reduced postoperative pain and a lower postoperative wound infection rate with the laparoscopic approach.

In all patients undergoing appendicectomy, prophylactic antibiotics should be used and a combination of metronidazole and cefuroxime is widely favoured. However there is evidence that metronidazole alone, administered as a suppository, is appropriate. In the patient who has a perforated appendix, appendicectomy should be followed by peritoneal lavage with saline containing an antibiotic (cefuroxime or tetracycline). When perforation has occurred it is common practice to continue intravenous antibiotics for 3–5 days postoperatively. Clinical trials have shown that drains do not confer any benefit and may indeed increase the incidence of wound infection.

Appendicitis can be treated conservatively by means of bed rest and intravenous antibiotics (cefuroxime and metronidazole) but the risk of perforation and widespread peritonitis on this regime is such that it cannot be recommended for routine use. However, in certain circumstances where surgery is impractical (e.g. on a ship without a surgeon on board), this may be the only feasible approach.

The treatment of patients presenting with an appendiceal mass is rather different. Although some surgeons favour an operative approach the majority will treat an appendix mass conservatively. If the patient has a fever and a high white count and the mass is tender these are indications that an abscess has formed. This can be confirmed by ultrasound or CT scanning and insertion of a percutaneous drain is the current treatment of choice. Occasionally this can be followed by the development of a faecal fistula but this is usually a low-output fistula which normally heals spontaneously. If percutaneous drainage is inadequate, it may be necessary to carry out operative drainage through an incision placed lateral to the mass.

If, on the other hand, a mass develops without the signs and symptoms of an abscess the best approach is conservative. However, it is important that the patient should be investigated and a barium enema about 2 months after the development of the mass is necessary to exclude other pathology, such as a caecal carcinoma. In patients who have had an appendix mass treated conservatively, about 15% will develop recurrent appendicitis. This should be explained to the patient and an interval appendicectomy can be carried out according to a decision made jointly by the patient and the surgeon.

When a patient has a laparoscopy or laparotomy which reveals an apparently normal appendix and no other pathology, there is some debate as to whether or not to carry out an appendicectomy. Given that the risk of developing appendicitis in adults is in the region of 0.04 and the risk from death from acute appendicitis is about one in 800, it seems reasonable to leave the appendix *in situ*. The reality is that when a normal appendix is seen at laparoscopy most surgeons skilled in laparoscopic appendicectomy tend to remove the appendix. Especially with the open approach most surgeons perform appendicectomy for the following reasons.

- If a scar is present in the right iliac fossa, a future assumption that appendicctomy has been carried out may be made.
- If the patient has recurring right iliac fossa pain, appendicectomy will rule out an important cause of the symptom.
- About 20% of normal-appearing appendices show microscopic evidence of mucosal ulceration and pus in the lumen.
- The majority of cases of carcinoid of the appendix occur in organs which look macroscopically normal.

Prognosis

The overall mortality rate of 0.2–0.8% from appendicitis is attributable to complications of the disease rather than to the surgical treatment. In children, the mortality rate ranges from 0.1% to 1%; in patients older than 70 years, the rate rises above 20%, primarily because of diagnostic and therapeutic delay. Appendiceal perforation is associated with increased morbidity and mortality.

Complications occur in 1–5% of patients with appendicitis, and postoperative wound infections account for almost one-third.

Neoplasms of the appendix

These are rare tumours and the vast majority present as acute appendicitis, with the diagnosis being established by histology. In this respect, it has been estimated that 1.0% of all appendicectomy specimens contain a neoplasm. The age-adjusted incidence of malignant neoplasms of the appendix is 0.12 cases per 100 000 population per year (SEER database). The gene alterations of non-carcinoid tumours of the appendix differ from those of colorectal carcinomas and consist of frequent K-*ras* proto-oncogene mutation without any alterations of *p53* tumour suppressor gene or MSI genotype. Pathologically there is an important distinction between mucinous (mucin secreting) and non-mucinous tumours of the appendix as both the clinical presentation and overall survival differ between the two groups. The five common histological types in order of descending frequency are:

- malignant carcinoid of the appendix
- GCC of the appendix
- colonic adenocarcinoma of the appendix
- mucinous adenoma/adenocarcinoma of the appendix
- signet ring carcinoma of the appendix.

Carcinoid tumours of the appendix

Carcinoids are the most common tumours of the appendix, with a peak incidence in the third and fourth decades of life. They are composed of neuroendocrine cells and exhibit variable biological behaviour from relatively benign to aggressively malignant. Carcinoid tumours are discovered in roughly one in every 300 routine appendicectomies for acute appendicitis. Occasionally carcinoid tumours secrete ACTH, and these may produce the Cushing syndrome. There is debate concerning the precise origin of carcinoid tumours: whether they arise from the Kulchitsky cells at the base of Lieberkuhn's glands or from similar cells in the lamina propria and submucosa in close association with nerves (subepithelial neuroendocrine complexes).

Carcinoids form small (70% <1.0 cm) fairly circumscribed but not encapsulated greyish white tumours, situated most commonly at the tip of the appendix (70%) giving rise to a 'bell clapper' configuration, in the body (22%) and the base (7%) of the organ.

Classical appendiceal carcinoids

Many reports on carcinoid tumours indicate that malignant carcinoids are more common in women, have a younger average age at diagnosis and, in general, a better overall survival than all other histological types of appendiceal tumours. The vast majority of classical appendiceal carcinoids are less than 1.0 cm in diameter and there has never been a reported case of metastases occurring from a tumour of this size. However, there is a clear risk of metastatic disease when a carcinoid is greater than 1.5 cm in diameter. Thus if the carcinoid exceeds 1.5 cm in diameter, a right hemicolectomy with radical removal of the ileocaecal lymph nodes is advisable. For tumours between 1.0 cm and 1.5 cm, right hemicolectomy is probably unnecessary as long as the resection margins after appendicectomy are clear. If a lesion in the appendix is encountered incidentally during an abdominal operation, the appendix should be removed and subjected to a frozen section. If this confirms a carcinoid tumour which is small (<1.0 cm), no further action is required, but if the lesion is greater than 1.5 cm, a right hemicolectomy should be performed.

Goblet cell carcinoids

GCCs account for less than 5% of tumours of the appendix and exhibit histological features of both adenocarcinoma and carcinoids and though they are more aggressive than conventional carcinoids, they exhibit considerable variation in biological aggressiveness in individual patients. The histopathological features indicative of invasive and metastatic behaviour include increased number of Paneth cells, excess mucin secretion and presence of pancreatic polypeptide.

GCC arises from a pluripotent cell (stem cell) with endodermal origin with neuroendocrine and mucinous differentiation (hence they are sometimes called amphicrine cell tumours). The component cells contain two types of granules: neuroendocrine and mucinous. The degree of mucin production varies from cells distended by mucin to discrete granules of mucin. Paneth cells are present in 30–50% of tumours and are associated with an increased risk for metastatic spread especially to the ovaries. Macroscopically, GCCs usually arise in the distal segment of the appendix (70%) from the lamina propria and then infiltrate the wall of the appendix without forming a distinct mass. The serosa and mesoappendix are involved in 20% and 50%, respectively, at the time of diagnosis. Metastases are rare when the disease does not extend beyond the muscularis propria.

Clinical features

A major review by Payam *et al.* based on 57 publications involving 600 patients indicates the mean age of presentation of GCC is 59 years, which is significantly older than the mean age of presentation of the classical carcinoids. The sex incidence is equal. The tumour is rarely diagnosed preoperatively. Its most common clinical presentation is with acute appendicitis (23%). Other manifestations include ill-defined lower abdominal pain (5%) and an appendicular mass (3%). In women, they may also present as Krukenberg tumours in the ovaries. Distant metastases are present at the time of diagnosis in 11%, with the ovaries being the most common site. Regional lymph node involvement is present in 9% of patients.

Surgical treatment

Appendicectomy is the treatment of choice in the majority of patients with no concomitant caecal involvement and low-grade tumour histology. A radical right hemicolectomy is however indicated in tumours with cellular de-differentiation, increased mitotic activity, and involvement of the base of the appendix with caecal wall infiltration, lymph node involvement and for tumour size greater than 1.5 cm. In addition to right hemicolectomy, some advocate bilateral oophorectomy in female patients because of the possibility of ovarian metastases.

Adjuvant therapy

Most of the regimes used include 5FU. Although 5FU is not used routinely by all centres, there is some evidence for its benefit in preventing peritoneal disease, and, for this reason, 5FU is recommended in all GCC patients.

Patients with residual macroscopic disease should be considered for cytoreductive surgery and intraperitoneal chemotherapy with either mitomycin C and 5FU or cisplatin and doxorubicin.

Patients with Krukenberg's tumours have been treated with cisplatin-based chemotherapy following excision with a survival benefit over surgery alone. One series with FOLFOX chemotherapy (oxaliplatin combined with 5FU and leucovorin) reported good partial and complete response with sustained remission in patients with metastasis to ovaries, peritoneal cavity and lymph nodes.

Prognosis of goblet cell carcinoid

This is estimated to be intermediate between classical carcinoids and well-differentiated adenocarcinomas of the appendix, although the outcome varies in the individual patient. Tumour characteristics that predict aggressive behaviour include size, histological subtype and mesoappendiceal involvement. Additionally, tumours larger than 2.0 cm are associated with a poorer prognosis. However, even smaller tumours do occasionally metastasize. However, the overall survival for GCC of the appendix is not significantly worse than that for patients with malignant carcinoid when adjusted for age and extent of disease at presentation. The reported average survival of GCC is 4.6 years with an extremely variable range of 6 months to 20 years.

Colonic adenocarcinoma of the appendix

Sometimes referred to as 'colonic-type adenocarcinoma of the appendix', this is similar to adenocarcinoma of the colon. It is an extremely rare tumour and accounts for approximately 15% of all malignant tumours of the appendix. When it occurs at the base of the appendix, it may be difficult to be sure whether it has arisen in the appendix or the caecum. It behaves more like colon cancer in its propensity to metastasize via the lymphatic nodal system and the bloodstream. It tends to be an aggressive tumour and 30% of these tumours have spread to the peritoneal cavity at the time of diagnosis. The disease is usually encountered in elderly people (60–70 years) and is commoner in males with a sex ratio of 2:1.

Clinical features

The majority of patients present with acute appendicitis, and in 50% of these the tumour is found to have perforated with local peritonitis. Other patients present with a hard mass in the right iliac fossa, pain and ascites. Cases with appendiceal perforation are likely to have seedling deposits and a high risk of intraperitoneal recurrence. The tumour often metastasizes to the ovaries in females, in whom an ovarian mass may be the first presentation of the disease.

Treatment

Surgical treatment consists of right hemicolectomy with or without bilateral salpingo-oophorectomy as a prophylaxis against Krukenberg tumours in females. Although there is some debate on the need for bilateral salpingo-oophorectomy, the high risk for metastatic disease in the ovaries is undeniable. Some also advocate the use of intraperitoneal chemotherapy in addition to a right hemicolectomy even in the absence of macroscopic disease within the peritoneal cavity after resection, especially for intermediate to high-grade tumours and in cases with perforation. Cytoreduction surgery and hyperthermic intraperitoneal chemotherapy are recommended for peritoneal metastasis or peritoneal carcinomatosis. Systemic chemotherapy is with regimens used for colon cancer (5FU, leucovorin, oxaliplatin, irinotecan etc.), although there have been no randomized trials to confirm a survival advantage of this chemotherapy for adenocarcinoma of the appendix. The antiangiogenic humanized monoclonal antibody Avastin has also been used but the reported experience is limited. The overall survival in the reported 5-year literature is 40–50%, but higher survival rates up to 80% have been reported in recent years even in patients with peritoneal disease after complete cytoreductive surgery and hyperthermic intraperitoneal chemotherapy.

Signet ring carcinoma of the appendix

Signet ring cell carcinomas (stomach, small bowel, colon, appendix) are composed of mucus-producing tumour cells with strong immunoreactivity against cytokeratin 20, CDX-2, MUC-2 (Mucin 2 coded by gene *Mc2*) and CEA, and focal immunopositivity for MUC-5AC (Mucin 5Ac coded by gene *Muc5a*). CDX-2 is a useful marker to confirm an appendiceal origin of pseudomyxoma peritonei (PMP). The *Cdx2* which encodes for CDX2 protein is a homeobox gene that is involved in the development of the small and large intestine and in the differentiation of intestinal epithelial cells. In adult humans, it is expressed in intestinal epithelial cells, where it acts as a transcription factor. The highest frequency of extensive CDX2 expression is seen in colorectal adenocarcinomas and mucinous appendiceal tumours. NETs of the gut also express CDX2, but the expression varies, being high in the midgut including the appendix (90%) and lower in the hindgut (44%).

Primary signet ring cell carcinoma of the appendix is exceedingly rare with an estimated incidence of 0.12 cases per 1 million people per year. Nonetheless it is considered separately from other carcinomas in view of its uniformly poor prognosis. This has been confirmed by many reported series with overall survival rates varying from 7% to 20%. As with other signet ring cell carcinomas (stomach and colon), patients with signet ring cell carcinoma of the appendix present with advanced disease that in part explains the bad prognosis. However, the signet ring cell morphology itself contributes to the poor clinical outcome even when tumour stage and disease extent are taken into account. The mean age of patients at presentation is 58 years and both sexes are affected equally. As with other tumours of the appendix, the usual presentation is with acute appendicitis and the diagnosis is established by histological examination the appendix.

Treatment

The standard surgical treatment is by right hemicolectomy. Routine bilateral salpingo-oophorectomy is advisable especially in postmenopausal females as, apart from assisting with tumour staging, it abolishes the risk of ovarian deposits which are common in signet ring tumours.

The treatment options for metastatic disease include systemic chemotherapy alone, cytoreductive surgery with peritonectomy with hyperthermic intraoperative intraperitoneal chemotherapy and combination of treatments. Of these, cytoreductive surgery and hyperthermic intraperitoneal chemotherapy have recently become the treatment of choice as for all types of mucinous-type tumours as it improves the survival rate and reduces the recurrence rate in patients with PMP. Increasingly cytoreduction and hyperthermic intraperitoneal chemotherapy is followed by systemic chemotherapy. The most important prognostic factor for survival is the completeness of cytoreduction. However, incomplete cytoreduction and perioperative intraperitoneal chemotherapy can achieve a limited long-term survival. Right hemicolectomy alone does not confer a survival advantage in patients with mucinous appendiceal tumours with peritoneal seeding and is not recommended in patients with inoperable peritoneal disease which precludes substantial cytoreduction.

Systemic chemotherapy is used on its own or after cytoreduction and intraperitoneal chemotherapy with agents used in intraperitoneal chemotherapy including mitomycin C, fluoropyrimidines and platinum compounds. Other regimens for systemic chemotherapy are based on 5FU, leucovorin and cisplatin/oxaliplatin (FOLFOX-4).

Mucinous neoplasms of the appendix

A simple mucocele of the appendix is a rare condition, which is thought to arise as a sequel to obstruction of the appendix without the onset of infection. The appendix becomes distended by mucoid secretion and the normal mucosa becomes replaced by a single layer of mucus-secreting cells. Eventually the lesion may calcify (Figure 29.33).

Mucocele of the appendix is no longer considered a benign tumour but is regarded as a low-grade borderline malignant lesion or, more appropriately, mucinous tumour of uncertain malignant potential (UMP) to distinguish it from the overtly more aggressive mucinous adenocarcinoma. In contrast to the latter, tumours in the UMP category appear benign on histology, rarely metastasize to lymph nodes and, although they may give rise to PMP, they rarely invade parenchymal organs except for the ovary or spread to regional lymph nodes. Thus PMP caused by UMP tumours (usually following rupture) carries a much better prognosis than in cases caused by mucinous adenocarcinomas.

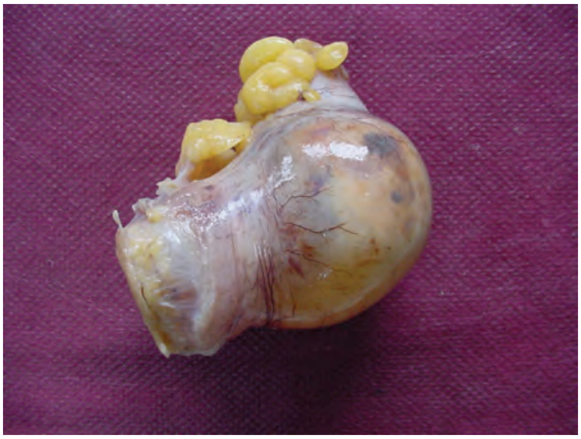

Figure 29.33 Benign mucocele of the appendix. (Courtesy of Professor Omar Shah, Srinagar, Kashmir India.)

One classification of appendiceal mucinous tumours proposed by Pai and Longacre qualifies the designation UMP for mucinous tumours of uncertain malignant potential with M-UMP for mucinous tumours which have spread to the pertinoneum but are clearly not invasive. The details of this classification are as follows.

1. *Adenoma*: simple or focally stratified columnar epithelium with goblet cells; mild to moderate atypia; no atypical mitosis, no stromal invasion, no extra-appendiceal epithelium – its oncological significance is that when completely excised without rupture it does not recur; but rupture may cause acellular mucinous ascites.
2. *Mucinous tumour of UMP*: as in 1 but (1) with involvement of proximal margin, (2) mucin with epithelium though present within the wall is not overtly invasive, (3) there is uncertainty on the presence of epithelium within extra-appendiceal mucin – its oncological significance relates to the risk of PMP and need for close follow-up.
3. *Mucinous tumour of M-LMP*: as in 1, but neoplastic cells are present in peritoneal implants. May require hyperthermic intraperitoneal chemotherapy.
4. *Mucinous adenocarcinoma:* a frankly invasive tumour which may cause aggressive PMP with visceral invasion and nodal metastases.

However, there are other classifications and there seems to be a lack of agreement amongst expert pathologists in defining a generally accepted classification and some have suggested a simpler histological grouping into (1) appendiceal mucinous neoplasm with low dysplasia, (2) appendiceal mucinous neoplasm with high-grade dysplasia and (3) invasive mucinous adenocarcinoma.

Clinical features

Mucinous tumours often present with acute appendicitis. Other presentations include abdominal distension from mucinous collection in the abdomen or pelvis or more generalized ‘mucinous ascites’. Females may present with ovarian masses

(Krukenberg tumours). Male patients may present with inguinal hernia caused by the increased intra-abdominal pressure.

Treatment

A 'benign' mucinous adenoma that has not ruptured and which is confined to the appendix is treated by appendicectomy with extreme care being taken to avoid rupture during removal especially if the laparoscopic approach is used when retrieval should be through a large enough wound to ensure against this complication.

Treatment for suspected mucinous adenocarcinoma confined to the appendix should be by *en bloc* removal of the appendix with the right colon. Systemic chemotherapy is used in addition for treatment of mucinous adenocarcinoma.

Mucin genes, which play an important role in the pathogenesis of PMP, are regulated by several mucin-encoding genes and by epidermal growth factor receptor. This has recently led to treatment of PMP with cetuximab monotherapy. PMP is considered in Chapter 21.

Meckel's diverticulum

Anatomy

A Meckel's diverticulum is a remnant of the vitellointestinal duct and is present in about 2% of the population. It arises from the antimesenteric side of the ileum. It has the same microscopic structure as the adjacent small bowel and it has a separate blood supply from the adjacent SBM (the omphalomesenteric artery). Although it is frequently said that most Meckel's diverticula are situated two feet (60 cm) from the ileocaecal valve, as many as 25% may be situated more proximally in the ileum. The length and shape of the diverticulum is highly variable and although 85% are blind-ended, the rest have an attachment which is related to its embryological origin. Two per cent of these exist as a patent vitellointestinal duct with a faecal fistula at the umbilicus. In 1%, the diverticulum is attached to the umbilicus by a band, and in about 10% of cases a band from the diverticulum is connected to the adjacent mesentery (a mesodiverticular band) (Figure 29.34).

Ectopic tissue is found within the Meckel's diverticulum in about 70% of cases. This is usually gastric mucosa, but it is also possible to find pancreatic, duodenal or colonic tissue. The presence of ectopic gastric mucosa has important implications for the clinical presentation of Meckel's diverticulum, as it is associated with peptic ulceration secondary to acid and pepsin secretion.

Pathology

The majority of Meckel's diverticula do not cause problems and remain asymptomatic. However, the following three pathological processes may occur as a result of a Meckel's diverticulum:

- inflammation of the diverticulum
- peptic ulceration of the small bowel
- intestinal obstruction.

Inflammation

Meckel's diverticulum can become inflamed in very much the same way as the vermiform appendix. Likewise, gangrene and perforation of the diverticulum may ensue.

Peptic ulceration

When there is heterotopic gastric mucosa within the lumen of the diverticulum (~40%) this secretes pepsin and hydrochloric acid. As a result peptic ulceration may occur, most commonly at the neck of the diverticulum or just distally in the ileum. The role of H. *pylori* in peptic ulceration related to a Meckel's diverticulum is not known.

Intestinal obstruction

Intestinal obstruction may result from intussusception occurring with the diverticulum acting as a lead point. It can also occur because of persistence of the band which was once the vitellointestinal duct producing a small bowel volvulus. In addition, entrapment of small bowel can occur through a defect caused by a mesodiverticular band or an omphalomesenteric artery.

Clinical features

The clinical presentation of asymptomatic Meckel's diverticulum depends on the underlying pathology.

Acute inflammation

Acute Meckel's diverticulitis produces a symptom complex which is very similar to appendicitis but normally the pain persists in the central abdominal area without a shift to the right lower quadrant. This usually occurs in children and frequently a diagnosis of acute appendicitis is made.

Peptic ulceration

Peptic ulceration of the neck of the Meckel's diverticulum or the ileum can lead to bleeding which presents either as melaena or fresh rectal bleeding. Again this nearly always occurs in children.

Intestinal obstruction

This may present with the typical clinical features of a small bowel obstruction. However, infarction of the bowel is likely with volvulus or entrapment of the small bowel by the band and in such cases the patient will become rapidly ill with a pyrexia and tachycardia, and be found to have peritonitis on examination.

Diagnosis

The diagnosis of Meckel's diverticulum is usually made at operation but in the child who is having repeated episodes of brisk rectal bleeding or melaena, a technetium scan may be of value. In this test, intravenous administration of ^{99m}Tc is followed by external scintiscanning. The radionuclide is taken up by the ectopic gastric mucosa. Mesenteric angiography may also be helpful in the presence of active bleeding.

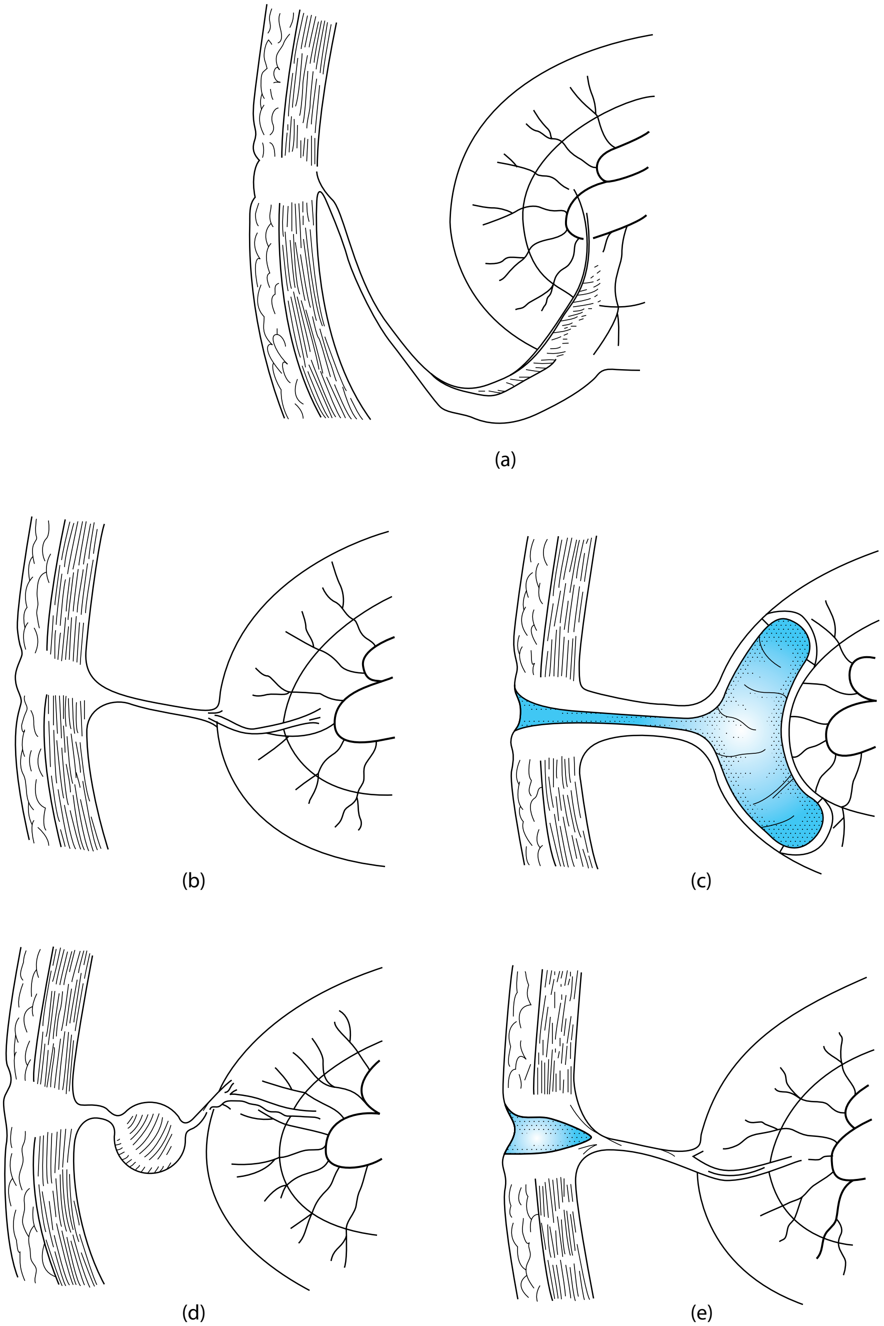

Figure 29.34 The vitellointestinal duct may connect with the umbilicus as (a) a fibrous cord extending from a Meckel's diverticulum; (b) a simple fibrous cord to a loop of ileum; (c) as an umbilical fistula; (d) a fibrous cord with a cyst; (e) an umbilical sinus.

Treatment

The standard treatment of a Meckel's diverticulum is excision of the diverticulum together with a wedge of the adjacent ileum. In some cases, however, with extensive inflammation of the diverticulum a limited small bowel resection may be necessary. If a Meckel's diverticulum is found incidentally during the course of a laparotomy/laparoscopy, removal is not necessary if the diverticulum has a wide base and feels soft on palpation. However, if the neck is narrow or nodules are palpable in the walls of the diverticulum, removal is advisable.

CHAPTER 30

Disorders of the colon and rectum

PARIS TEKKIS, PANAYIOTIS GEORGIOU, EDWARD FITZGERALD AND EMIL TAN

Anatomy

The large intestine consists of the caecum, vermiform appendix, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid colon, rectum and anal canal (Figure 30.1). The anatomy of the appendix and anal canal is dealt with separately in the appropriate chapters.

Originally a mid-line structure, the large intestine undergoes rotation during embryological development and as a result the ascending colon and the descending colon are essentially retroperitoneal structures. However, the degree to which the large intestine has a mesentery is highly variable as is its total length that averages 1.5 m. The whole of the large intestine is capable of considerable distension, although in an adult living in the Western world the left side of the colon tends to be less distensible than the right owing to muscular hypertrophy.

The caecum lies in the right iliac fossa and is approximately 7 cm in length and width. Proximally it becomes the ascending colon at its junction with the terminal ileum. The caecum lies on the iliac and psoas muscles and on the genitofemoral, femoral and lateral cutaneous nerves. It also lies anterior to the testicular or ovarian vessels and the ureter. The exact position of the caecum is variable and it may extend into the true pelvis. The caecum is almost completely surrounded by peritoneum but it is often attached to the iliac fossa medially and laterally. This can produce a retrocaecal peritoneal recess which may extend upwards posterior to the ascending colon.

The ileocaecal junction is extremely variable in appearance. In most circumstances the ileum enters obliquely into the large bowel through a horizontal slit and is partly invaginated into the caecum to form a fold (the ileocaecal valve). Reflux of caecal contents into the small bowel is prevented by contraction of the circular muscle of the ileum which leads to closure of the ileocaecal valve. However, the muscle in the valve is poorly developed and the ileocaecal valve is frequently incompetent.

The ascending colon varies from about 10 to 20 cm in length. It lies on the iliac muscle, the iliac crest and quadratus lumborum, crossing the lateral cutaneous nerve of the thigh, the ilioinguinal and iliohypogastric nerves. It ends at the hepatic flexure where the large bowel turns to the left on the lower portion of the right kidney inferior to the liver. Under most circumstances peritoneum covers the front and the sides of the ascending colon and fixes it firmly to the posterior abdominal wall, but occasionally there is a short mesentery.

The transverse colon is the longest section of the colon varying from 40 to 70 cm in length. It extends from the hepatic flexure to the splenic flexure and forms a dependent loop between both of these points. The lowest point of the transverse colon may reach below the umbilicus, although it is usually just superior to it. The transverse colon is suspended by the transverse mesocolon which is fused to the posterior surface of the greater omentum. This transverse mesocolon is attached to the descending part of the duodenum, to the head and the lower aspect of the body of the pancreas and to the anterior surface of the left kidney. It contains both the middle colic vessels and branches of the right and left colic

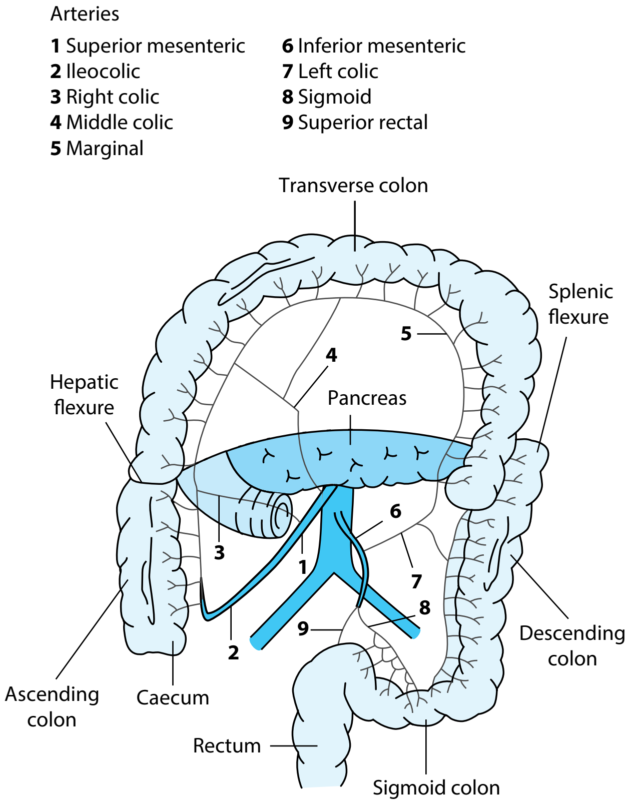

Figure 30.1 The large intestine and its blood supply.

vessels with associated nerves and lymphatics. Thus the transverse colon starts immediately anterior to the descending part of the duodenum and the head of the pancreas, descends anterior to the small intestine and ascends to the splenic flexure. At this point it is anterior to the left part of the left kidney and immediately below the spleen. The splenic flexure is attached to the diaphragm by peritoneum (phrenicocolic ligament) and can be extremely close to the spleen. At this point the greater omentum frequently has attachments to the spleen and is closely associated with the colon. Traction on these splenic attachments may cause splenic bleeding in the course of mobilization of the splenic flexure.

The descending colon extends from the splenic flexure to the rim of the true pelvis close to the inguinal ligament. The descending colon is attached by peritoneum to the posterior abdominal wall in the left paravertebral gutter and iliac fossa. Superiorly it is anterior to the lateral surface of the left kidney and medial to the diaphragm, and then it lies on the same muscles and nerves as the ascending colon. At the anterior superior iliac spine, the descending colon turns medially, superior to the inguinal ligament, and lies on the femoral nerve, psoas muscle and the genital vessels, and becomes the sigmoid colon immediately anterior to the external iliac vessels.

The sigmoid colon is the most variable part of the colon in terms of its length (50–80 cm) and its mobility. It extends from the end of the descending colon to the rim of the true pelvis where it becomes the rectum. It has a long mesentery (the sigmoid mesocolon) which has quite a short base starting at the end of the descending colon and ascending on the external iliac vessels to the mid - point of the common iliac artery. At this point it turns downwards and to the right to the rim of the true pelvis. The mesocolon contains the sigmoid branches of the inferior mesenteric artery and associated nerves and lymphatics. Under normal circumstances the sigmoid colon lies entirely in the left iliac fossa and the true pelvis but it may also extend across to the right iliac fossa.

The rectum is that part of the large bowel which lies in the true pelvis at the point where the sigmoid mesocolon ends. Again, this is highly variable in length depending very much on the build of the individual but it is said to be 15 cm long as measured by a rigid sigmoidoscope. It follows the curve of the sacrum and the coccyx and then runs anteriorly and inferiorly to the central perineal tendon lying on the anococcygeal ligament and the levator ani muscles. It then ends by turning posteriorly and inferiorly as the anal canal, immediately posterior to the central perineal tendon and to the apex of the prostate in the male. The lowest part of the rectum is more capacious than the rest and is known as the ampulla. The rectum is not straight; in the sagittal plane it follows the curve of the sacrum and coccyx and in the coronal plane it is S shaped. This gives rise to prominent folds within the lumen of the rectum known as the valves of Houston. The front and the sides of the upper third of the rectum are covered with peritoneum but this gradually moves anteriorly and turns off the front of the rectum at the junction between its middle and lower thirds. This forms the rectouterine or rectovesical pouch by passing upwards on the back of the posterior fornix of the vagina or the back of the bladder respectively in the female and the male. In its lower third, the rectum lies behind the base of the bladder, the seminal vesicles and the prostate in the male and behind the vagina in the female.

In both sexes the rectum and its surrounding areolar tissue is separated from the anterior structures by a fascial layer known as Denonvilliers' fascia. Posteriorly the rectum is separated from the sacrum and the coccyx and anococcygeal ligament and the muscles attached to these (piriformis and levator ani) by a layer of pelvic fascia. This fascia is known as Waldeyer's fascia. In its upper two-thirds the actual muscular wall of the rectum is separated from the pelvic fascia by a posterior cushion of areolar tissue which becomes circumferential below the rectouterine or rectovesical pouch. This carries the blood supply to the rectum and its lymphatic drainage and is known as the mesorectum (Figure 30.2). Inferiorly and posteriorly the mesorectum has a bilobed structure.

Taeniae coli

The taeniae coli are three ribbon-like thickenings of the otherwise thin longitudinal muscle of the large bowel which arise from the longitudinal muscle at the root of the vermiform appendix and end by spreading out at the end of the sigmoid colon to become continuous with the thicker longitudinal muscle of the rectum. These three taeniae are spaced out uniformly around the circumference of the colon and between them the wall of the colon bulges outwards forming pouches or sacculations. In the ascending colon and descending colon, the taeniae are anterior, posteromedial and posterolateral, whereas in the transverse colon the positions become posterior, superior and anterior.

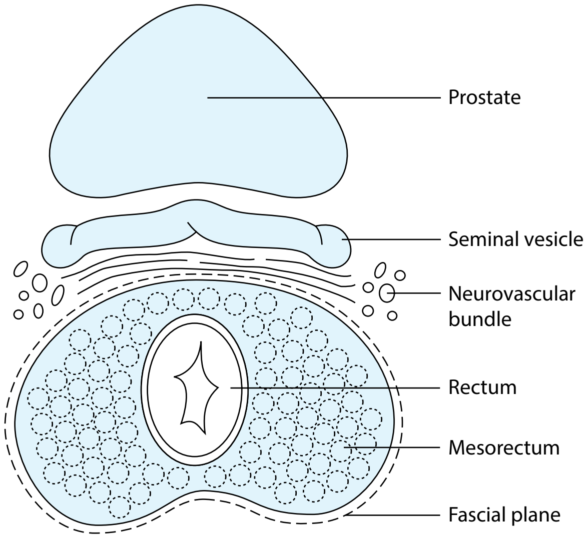

Figure 30.2 Cross-section of the rectum at the level of the seminal vesicles showing the mesorectum.

Blood supply of the large intestine

The most important vessels involved in the blood supply of the colon are the superior mesenteric artery, the inferior mesenteric artery and the marginal artery, which supplies an anastomosis between these two vessels (Figure 30.1). The superior mesenteric artery originates from the aorta just below the coeliac axis and passes posterior to the pancreas. Its terminal branch which supplies the caecum is known as the ileocolic artery. Its other named main branches which supply the colon are the right colic artery, which supplies the ascending colon, and the middle colic artery, which runs in the transverse mesocolon to supply the transverse colon. The inferior mesenteric artery arises from the aorta just inferior to the third part of the duodenum and descends on the left side of the aorta posterior to the peritoneum. Its first branch is the left colic artery which passes to the left and divides into ascending and descending branches. The ascending branch supplies the left side of the transverse colon and the splenic flexure, whereas the descending branch supplies the descending colon. The inferior mesenteric artery terminates at the base of the sigmoid mesocolon where it divides into sigmoid branches supplying the sigmoid colon and the superior rectal artery, which descends in the mesorectum to supply the upper part of the rectum. The marginal artery runs along the ascending, transverse and descending colons, receiving branches from the other colic arteries so that under normal circumstances ligation of any one of the main colic arteries would not result in ischaemia of any part of the colon. It must be remembered, however, that the marginal artery can become quite tenuous at the splenic flexure and continuity of the blood supply may be maintained by the ascending and descending branches of the left colic artery. It is therefore imperative that these two vessels are preserved when dividing either the left colic artery or the inferior mesenteric trunk during mobilization of the colon.

As mentioned above, the upper part of the rectum derives its blood supply from the superior rectal artery which is a terminal branch of the inferior mesenteric artery, but the lower rectum receives blood from the two middle rectal (or haemorrhoidal) arteries coming from the internal iliac arteries and two inferior rectal arteries which originate from the internal pudendal arteries in the ischiorectal fossae. The internal pudendal artery is itself a branch of the internal iliac artery.

The venous drainage of the large intestine follows its arterial blood supply but of course empties into the portal venous system. The inferior mesenteric vein diverges from the inferior mesenteric artery and passes up behind the pancreas to join the splenic vein. The superior mesenteric vein lies to the right of the superior mesenteric artery and joins the splenic vein at its junction with the portal vein behind the neck of the pancreas.

The lymphatic drainage of the large intestine also follows the blood supply. Small lymph nodes lie close to the marginal artery and also along the arteries leading towards it. The lymph draining through the lymph nodes associated with the branches of the superior mesenteric arteries passes into the intestinal trunk which lies in the root of the small bowel mesentery. The lymph nodes associated with the inferior mesenteric artery drain into the lumbar lymph nodes beside the aorta. Both of these empty into the cisterna chyli which enters the posterior thorax via the diaphragmatic hiatus.

Nerve supply of the large intestine

The nerve supply of the colon and the rectum, like the lymphatics, follows the course of the main vessels. The right colon receives sympathetic nerve fibres from the lower six dorsal ganglia via the superior mesenteric plexus and parasympathetic fibres from the coeliac branch of the posterior vagus nerve. The left colon and rectum are supplied through the upper three lumbar ganglia via the inferior mesenteric, superior hypogastric and inferior hypogastric plexuses (Figure 30.3). The latter plexus also receives branches from the sacral parasympathetic nerves (nervi erigentes). These nerves remain outside the pelvic fascia and are sometimes injured during mobilization of the rectum.

Physiology of the colon and rectum

Absorption acid excretion

About 1000 mL of ileal contents containing 90% water are discharged into the caecum every day in the normal adult. Water absorption takes place during transit through the colon, and only 100–200 mL of water is excreted in the faeces. The absorptive capacity of the colon depends on the rate at which ileal contents enter the caecum, and is greater in the right colon than in the left. Normal faeces are composed of 70% water and 30% solids; about 50% of the solids are bacteria and the remainder is composed of food waste and desquamated epithelium.

Nutrients such as glucose, amino acids, fatty acids and vitamins can be absorbed slowly through the colonic wall, but only very small amounts of these substances actually reach the caecum under normal circumstances. Sodium absorption is very efficient and is maintained by an active transport mechanism enhanced by mineralocorticoids and glucocorticoids. A normal adult can remain in sodium balance with as little as 5 mmol of

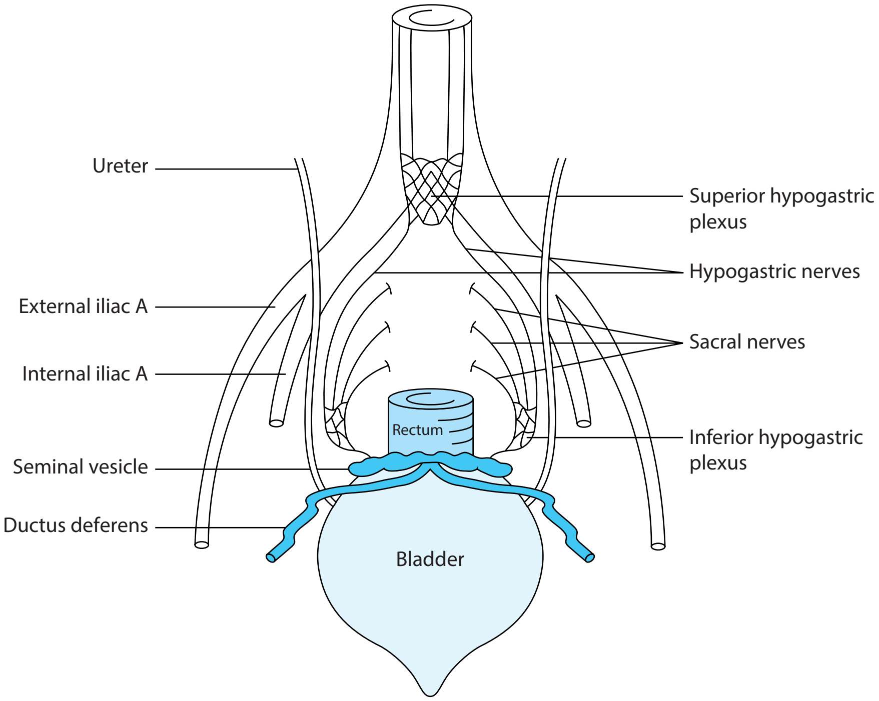

Figure 30.3 The autonomic nerves of the pelvis.

sodium per day in the diet, but following total colectomy and ileostomy the minimum daily requirement increases to about 100 mmol to offset losses from the stoma. Chloride and water absorption is passive and follows electrical and osmotic gradients established by the sodium pump.

Potassium is actively excreted into the faeces against a concentration gradient and by secretion in mucus. Excessive mucus production (e.g. in colitis or in villous adenomas) may lead to enormous losses of potassium. Only a small amount of bicarbonate is secreted into the colonic lumen in exchange for chloride.

A normal bowel habit is hard to define since it is influenced by social and dietary customs. The frequency of bowel movement in Western countries ranges from every 8 hours to once every 2–3 days. Any persistent change in bowel habit is an indication for investigation to exclude organic disease. Diarrhoea may be defined as stools containing more than 300 mL of fluid daily, although again this is highly variable. When excessive, it may be debilitating and even fatal if associated with large losses of fluid and electrolytes which are not replaced. Inflammatory disease of the colon or small bowel mucosa may cause excessive exudation of fluid and also lead to diarrhoea, as does anything that decreases the intestinal transit time and decreases absorptive surface area. The symptom of constipation has different meanings for different individuals. It may imply infrequency of bowel movements, hard consistence of the stools or difficulty in evacuation. The pathologies leading to diarrhoea and constipation are dealt with later in the chapter.

Colonic motility

There are three patterns of motor activity in the colon:

- *Segmentation.* This is the most common type of motor activity seen in the transverse and descending colon and consists of annular contractions that divide the lumen into segments propelling faeces over short distances in both directions. Segmental contractions form, relax and re-form in different locations in a random fashion, three to eight times per minute.
- *Mass movements.* These consist of strong contractions moving distally over relatively short distances (30–45 cm) in the transverse and descending colon. These are infrequent and probably occur only a few times each day, often in response to a meal.
- *Retrograde peristalsis.* This consists of annular contractions moving proximally in the right colon and in the sigmoid and descending colon. This is more frequently seen in experimental animals than in man. The retrograde movement can be shown by observing the spontaneous movement of a radio-opaque marker from the left to right colon.

A complex neurohormonal mechanism is involved in the colonic response to eating which has been inaccurately described as the gastrocolic reflex. This response consists of increased ileal emptying, increased mass movements and an urge to defecate. Other factors influencing colonic motility are physical activity, emotional states and faecal bulk. Thus normal colonic emptying is slow, complex and exceedingly variable. It is difficult to define altered motility in diseased states. There is no orderly laminar flow; some of the material entering the caecum flows past faecal material which has remained from earlier time periods. In general, residue from a meal reaches the caecum after 4 hours and the rectosigmoid by 24 hours. Since there is a large amount of mixing of bowel contents in the colon, residue from a single meal may be passed in the stool for 3–4 days afterwards under normal circumstances.

Intraluminal pressure studies of the colon can be performed by the use of small balloons, fine open-ended catheters or telemetry capsules. Such studies indicate that, although pressures of up to 100 mmHg can be generated, faecal transport can take place without a rise in intraluminal pressure. However, because specific patterns cannot be correlated with defined diseased states these investigations have little clinical significance. Rhythmic changes in the electrical potential in colonic muscle occur normally at two frequencies, three and nine per minute, respectively. The frequency appears to be approximately 16 per minute in the sigmoid colon with diverticular disease.

Microbiology of the large intestine

The normal faecal flora exists in a symbiotic relationship with the human host and supports several physiological processes. Bile pigments are degraded by colonic bacteria to give the stool its brown colour. Characteristic faecal odour is due to the amines indole and skatole, which are produced by bacterial action. Colonic bacteria also supply vitamin K to the host, alter both colonic motility and absorption and may be important in the defence against potentially more pathogenic organisms. Faecal bacteria deconjugate bile salts to produce free bile acids and also alter the steroid nucleus. These bacteria have been implicated in the pathophysiology of a variety of disease processes including the pathogenesis of carcinoma of the large bowel.

The colon of the fetus is sterile and bacterial colonization occurs soon after birth. The bacterial flora present in the colon varies with dietary and environmental factors, but over 99% of the normal flora is anaerobic. *Bacteroides fragilis* is the most prevalent. *Lactobacillus bifidus*, clostridia of various types and cocci of various types form the other common anaerobes. Aerobic bacteria can be divided into two groups, coliforms and enterococci. *Escherichia coli* is the predominant coliform and is present in counts of around 10^7 per gram of wet faeces. *Streptococcus faecalis* is the principal enterococcus and is present in similar numbers.

The bacterial flora of the colon is readily altered by antibiotic administration. Oral neomycin and tetracycline result in resistant R-factor enterococci and resistant staphylococci and bacteroides. Outbreaks of staphylococcal enterocolitis and more commonly pseudomembranous colitis from *Clostridium difficile* are frequently seen in surgical units.

Investigations

The main techniques used in the investigation of colorectal disease (excluding anorectal problems) can be subdivided into endoscopy and radiology. Under these headings the following procedures will be considered: rigid endoscopy, flexible endoscopy, barium enema, radio-opaque marker studies, colonic scintigraphy, ultrasound, CT scanning and MRI.

Rigid endoscopy

Rigid endoscopy is only of value in examining the anal canal and rectum and in the UK the nomenclature for describing the appropriate instruments is confusing. The term proctoscope refers to a short instrument which is only really of value in examining the anal canal, and this will be described in the appropriate section. The term rigid sigmoidoscope is the term used to describe the 25 cm long instrument which is used in association with a fibreoptic light source and insufflating bellows (Figure 30.4). Although reusable metal instruments are available most outpatient departments now use disposable plastic instruments which can be self-lubricating. This allows multiple examinations to be performed without the risk of infection and the need for cleansing and sterilizing the instrument. In addition, the attachment between the instrument and the bellows should be protected by a filtering device which will prevent infective agents being harboured in the bellows.

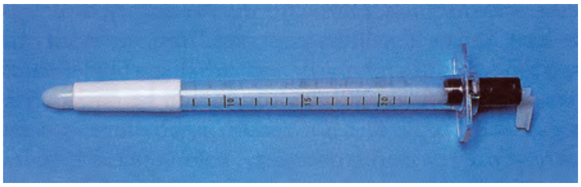

Figure 30.4 Rigid sigmoidoscope.

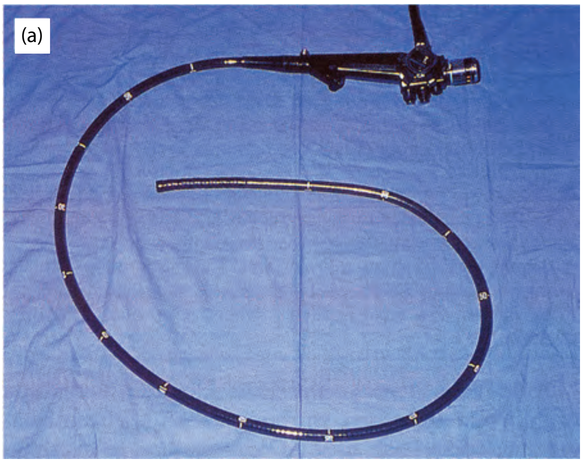
The term sigmoidoscope is misleading as only the very distal part of the sigmoid can be examined by the instrument and in most cases it is impractical to pass the instrument much beyond 15 cm. Under most circumstances the rigid instrument is used in unprepared bowel; although this may make the investigation difficult and sometimes impossible, it is useful to be able to see whether there is any blood staining on the faecal material. The other major advantage of rigid sigmoidoscopy is that it allows the operator to determine the exact position of a rectal lesion, i.e. whether it is on the anterior, posterior, right or left lateral walls of the rectum. This is essential information when considering transanal excision of a rectal tumour as the positioning of the patient on the operating table will depend on the exact site of the tumour. Aside from this, rigid sigmoidoscopy has no advantages over flexible endoscopy and it has several disadvantages. First, it is more uncomfortable; second, examination is limited to the rectum; third, it is difficult to see behind mucosal folds; and, fourth, it can be very difficult to see lesions just inside the anal canal.

Nevertheless, the instrument is widely used in outpatient departments as it offers the surgeon a rapid method of examining the rectum to look for tumours or mucosal inflammation. When carrying out an examination it is important to bear in mind the slightly anterior direction of the anal canal and then the sharp posterior angulation of the rectum, followed by the curve of the sacrum. Whenever pain is encountered the examination should be terminated immediately. When biopsies are taken using a rigid sigmoidoscope it must be remembered that the biopsy forceps are much larger than those used with flexible instruments, and care must be taken not to cause full - thickness damage to the rectal wall, particularly anteriorly where a perforation may occur.

Flexible endoscopy

The two types of flexible endoscope available are the sigmoidoscope and the colonoscope. The flexible sigmoidoscope is a 60 cm instrument, which is designed to examine no further



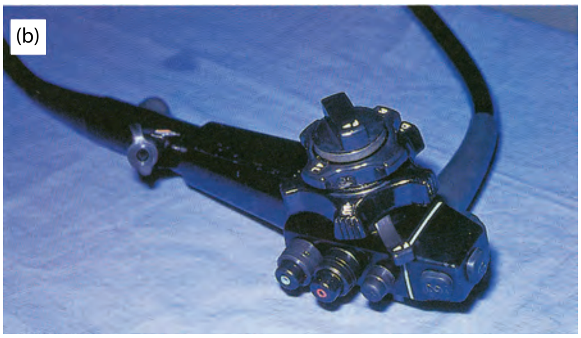


Figure 30.5 (a) A fibreoptic colonoscope. (b) The operating head of a video colonoscope. Note the absence of an eyepiece.

than the descending colon. The colonoscope (Figure 30.5), on the other hand, is a longer instrument, varying from 120 to 180 cm in length and is designed to reach the caecum. Flexible endoscopes are based on fibreoptic technology, and more recently videoendoscopes which incorporate a chip camera in the distal end of the instrument have come to the fore. In the latter, a digital image is displayed on a video monitor without an eyepiece optical interface.

The technique of flexible sigmoidoscopy is essentially similar to that of the first part of colonoscopy and therefore separate descriptions of the two procedures are not necessary. However, it is conventional for flexible sigmoidoscopy to be done without sedation whereas most endoscopists will use some form of sedation for colonoscopy as both insufflation of the large bowel and looping of the colonoscope can cause considerable discomfort. It is however essential that the patient should be able to respond to pain as this is an important signal to the endoscopist that the procedure may be about to cause damage to the colon.

Although there are many different forms of sedation it is the authors' preference to use an intravenous combination of an opiate (pethidine) and a benzodiazepine (Diazemuls). The sedation produced is profound and it is essential that secure venous access is obtained and the patient's oxygen saturation is continuously measured by pulse oximetry. It is also essential that antagonists to both opiates (nalaxone) and benzodiazepines (flumazenil) are readily available.

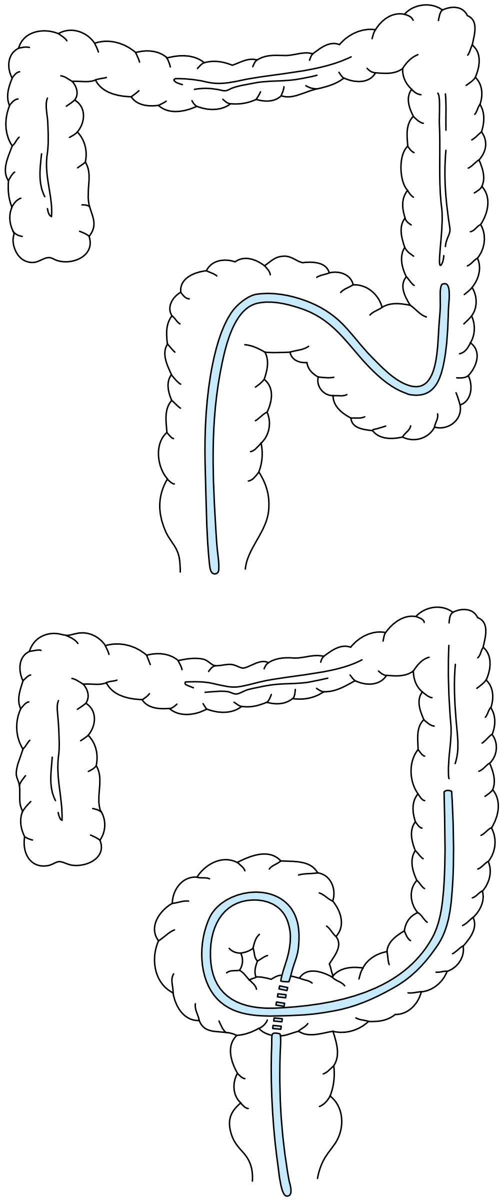

Figure 30.6 The N loop and the α loop.

The examination begins conventionally with the patient lying in the left lateral position. The rectum is usually easy to negotiate but at the rectosigmoid junction it may be necessary to pass the tip of the colonoscope 'blindly' to gain access to the sigmoid colon. This is a hazardous manoeuvre, particularly in the patient who has had previous pelvic surgery leading to adhesions, as perforation of the colon can occur. It must therefore be carried out with the utmost gentleness. In the sigmoid colon the colonoscope may assume either an N loop or an α loop (Figure 30.6). Once a loop like this has formed it is necessary to straighten the endoscope by pulling back and applying clockwise torque (Figure 30.7). The colonoscope should then be advanced maintaining the torque. If clockwise torque does not work, it is worth trying anticlockwise torque.

It is then usually a straightforward procedure to reach the splenic flexure but advancing the endoscope along the transverse colon may be difficult because of the formation of a further

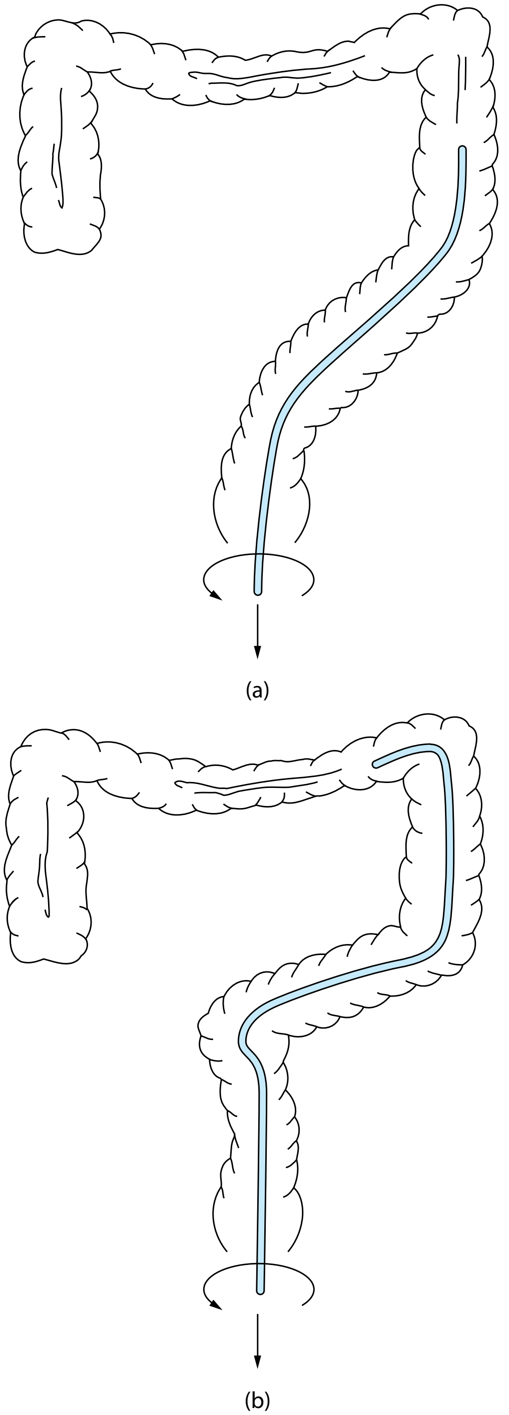

Figure 30.7 Straightening a sigmoid N loop (a) and α loop (b).

loop (Figure 30.8). This again may be overcome by withdrawing the colonoscope and it often helps to turn the patient on to his or her back. Throughout this procedure it is important not to overinsufflate the colon and regular withdrawal of the colonoscope with suction will 'concertina' the colon over the colonoscope. When the hepatic flexure has been reached a useful manoeuvre is to angle the tip of the colonoscope into the ascending colon and apply suction. This will often bring the caecum up to the tip of the colonoscope. If this is unsuccessful then turning the patient on to their right side (facing the endoscopist) may be a useful manoeuvre.

It is very important to recognize when the caecum has been reached and the only two really definite landmarks are the ileocaecal valve and the appendix orifice. Ideally the ileocaecal valve should be entered and a biopsy taken of the ileal mucosa to prove completion of colonoscopy but this is a tricky and time-consuming manoeuvre and few endoscopists would recommend doing this routinely. It must be emphasized that the anal canal and the caecum are the only two parts of the large bowel which can be identified unequivocally during colonoscopy, and even the most experienced colonoscopist will have difficulty in identifying the exact anatomical location of a lesion lying within the colon if it is not in the lower rectum or the caecum.

Complications of colonoscopy

The main complications of colonoscopy are perforation, haemorrhage, bacteraemia and cardiac arrhythmias. Perforation may result at the tip of the instrument or at the apex of a stretched loop (Figure 30.9). Perforation should always be suspected if there is bleeding or if fat can be seen through the wall of the colon. Obviously when small bowel loops can be seen the diagnosis is not in doubt. Perforation can also occur after polypectomy (see section Polyps) but this may be delayed. Likewise hot biopsy (see section Polyps) may lead to delayed perforation. The incidence of perforation is about 0.1% and all patients undergoing colonoscopy should have this risk explained.

Haemorrhage is nearly always a consequence of polypectomy. Significant haemorrhage after an ordinary colonoscopic biopsy is unlikely unless the patient has a coagulation disorder. Bacteraemia has been shown to occur after colonoscopy and it is therefore necessary to use intravenous antibiotics in patients with pacemakers and artificial or diseased cardiac valves. Cardiac arrhythmias commonly occur during colonoscopy but they are usually insignificant and self - limiting. It is however important that patients with cardiac disease should have continuous electrocardiogram (ECG) monitoring and it is essential that resuscitation equipment is present when colonoscopy is being performed.

Colonoscopy with PillCam Colon: capsule colonoscopy

The PillCam Colon (Given Imaging) capsule (31 × 11 mm) introduced in 2008 has two cameras (one at each end), each with a frame rate of four images per second and a battery life of 10 hours. To save power, the device can function in a preprogrammed delay mode keeping the capsule switched off until it reaches the colon. Special software enables the position of the capsule to be monitored during its transit through the gastrointestinal tract to be monitored and helps to identify the optimum time for administration of an additional dose of sodium phosphate to facilitate its transit. Special bowel preparation for capsule colonscopy (CC) is necessary to ensure a clean colon as irrigation for lens cleaning is not possible.

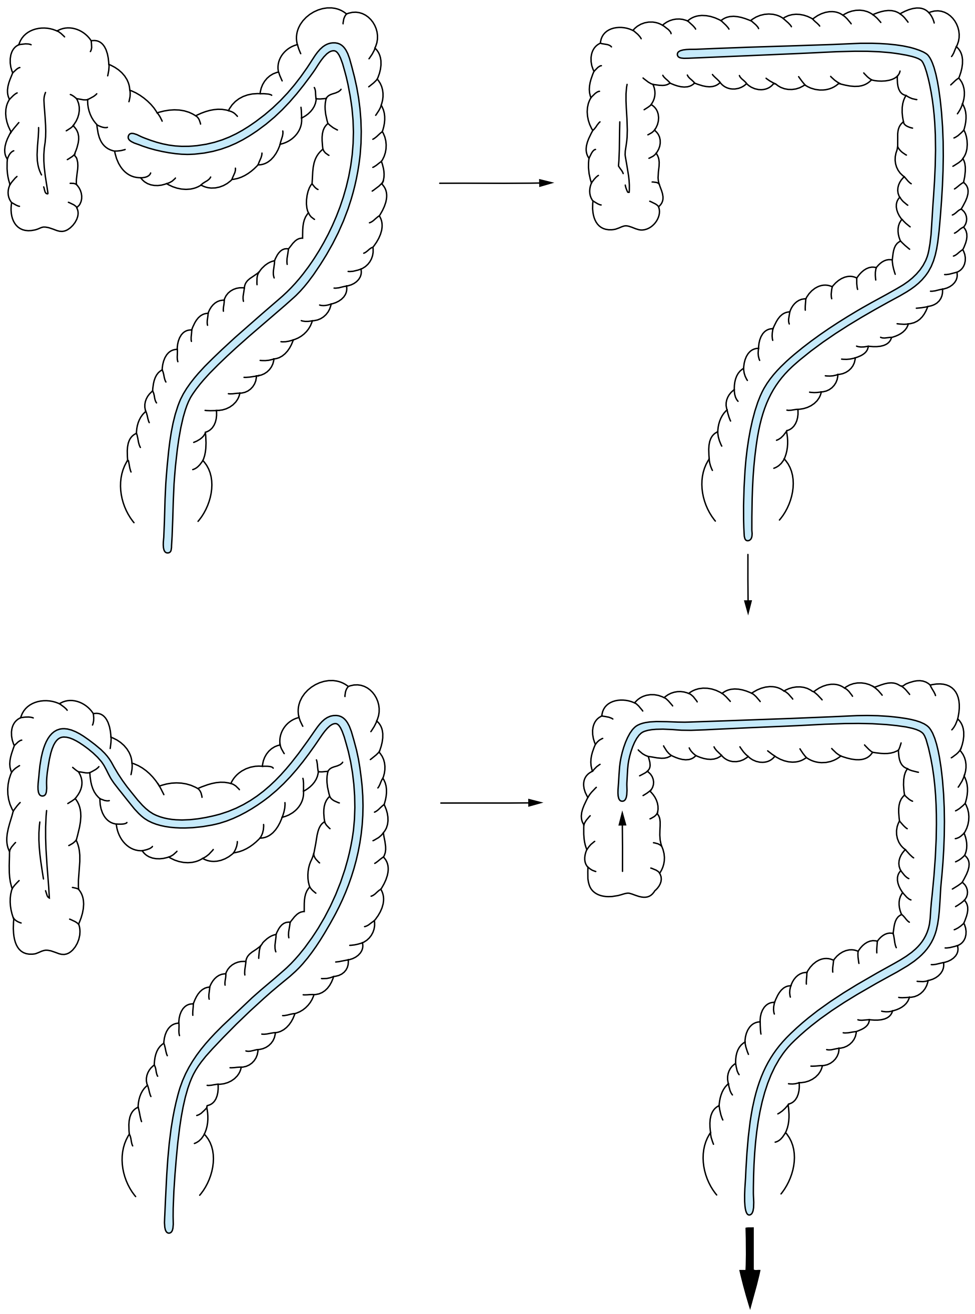

Figure 30.8 Progression of the colonoscope along the transverse colon.

This consists of a combination of diet, PeG-based solution, oral sodium phosphate, oral prokinetic and a rectal suppository. The liquid diet is commenced 1 day prior to the examination and kept until ingestion of the PeG-based solution. The patient ingests the capsule on the day of examination together with a dose of sodium phosphate. A second dose of sodium phosphate may be administered to facilitate capsule transit.

Detection of colonic polyps and colon cancer by CC

In the first multicentre, prospective study of PillCam Colon Ce, which involved 84 patients, CC provided a diagnostic yield of 76% compared with 80% achieved by flexible colonoscopy in the detection of polyps of any size. CC identified major lesions (polyps ≥ 6 mm) in 14 patients, whereas colonoscopy identified major lesions in 16 patients. The sensitivity of the CC reported by the three investigators who examined the data (in blinded fashion) ranged from 50% to 70%, whereas specificity ranged from 83% to 100%. In a single - centre, prospective study of 36 patients, CC detected polyps in 64% of patients compared with 69% detected by colonoscopy. For major lesions, the sensitivity and specificity were 60% and 73%, respectively. Currently, CC is used to complement flexible colonoscopy, being indicated in the rare instances when colonoscopy is refused by the patient or contraindicated because of comorbidities that preclude safe sedation of the patient. However, CC in its present form has major limitations: many patients are unwilling to undergo the procedure

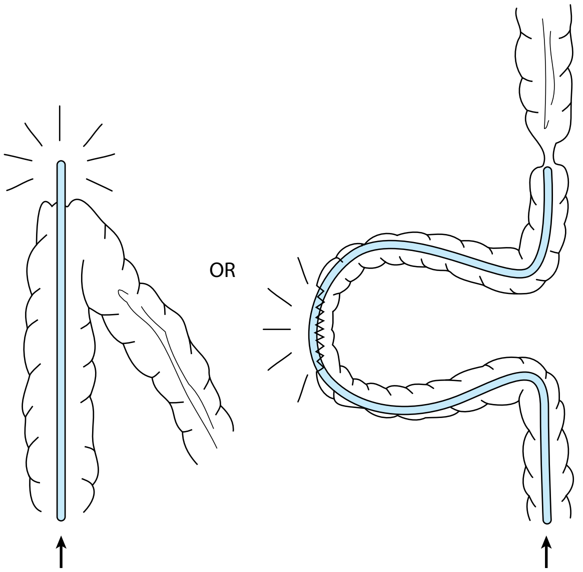

Figure 30.9 Colonoscopic perforation.

because of the complexity of the bowel preparation regimen (as the colon has to be completely clear of all faecal matter), passive transit and inability to biopsy lesions. In addition, technological improvements are necessary to enable the endoscopist to locate lesions and determine the size of polyps. Barring technological developments to overcome these limitations, it seems unlikely that CC will play a significant role or replace conventional colonoscopy in colorectal cancer screening in the short to medium term. The future in this respect lies in microrobotic systems capable of locomotion, imaging and biopsy.

Plain radiology

Plain abdominal radiograph films are particularly useful in the emergency situation. In the patient with mechanical large bowel obstruction, a typical gas pattern will be seen with obvious haustration (Figure 30.10). Pseudo-obstruction may be difficult to distinguish from mechanical obstruction although, in the former, the colonic dilatation usually ends in the region of the proximal descending colon. Obstruction due to volvulus of the sigmoid colon or the caecum will show a typical pattern and in patients with ischaemic colitis typical 'thumb printing' is seen when plain abdominal radiographs are obtained. In the emergency situation an erect chest radiograph should also be carried out. This can be scrutinized for gas under the diaphragm. The plain abdominal radiograph is also essential in patients with an acute exacerbation of ulcerative colitis or Crohn's colitis as this will help in making the diagnosis of toxic megacolon.

Barium enema

The mainstay of radiological investigation of the large bowel is the barium enema. Nowadays, this is always carried out as a double contrast study, i.e. with barium and insufflated air. This coats the colonic mucosa with barium allowing radiologists to detect small lesions and mucosal ulceration. Barium enemas are excellent for diagnosing carcinoma of the colon (Figure 30.11) but caution must be exercised in interpreting appearances in the sigmoid colon and in the caecum. In a redundant sigmoid colon with multiple overlapping loops of bowel, particularly if affected by severe diverticular disease, lesions may be missed (Figure 30.12). Conversely, there tends to be a problem with over-reporting carcinomas in the caecum where prolonged spasm may mimic suspicious appearances (Figure 30.13). Thus in the patient with suspicious symptoms who has a normal looking sigmoid colon, a flexible sigmoidoscopy is mandatory. Likewise in the asymptomatic patient who is not anaemic, a diagnosis of carcinoma of the caecum should be confirmed by colonoscopy unless the appearances are absolutely unequivocal.

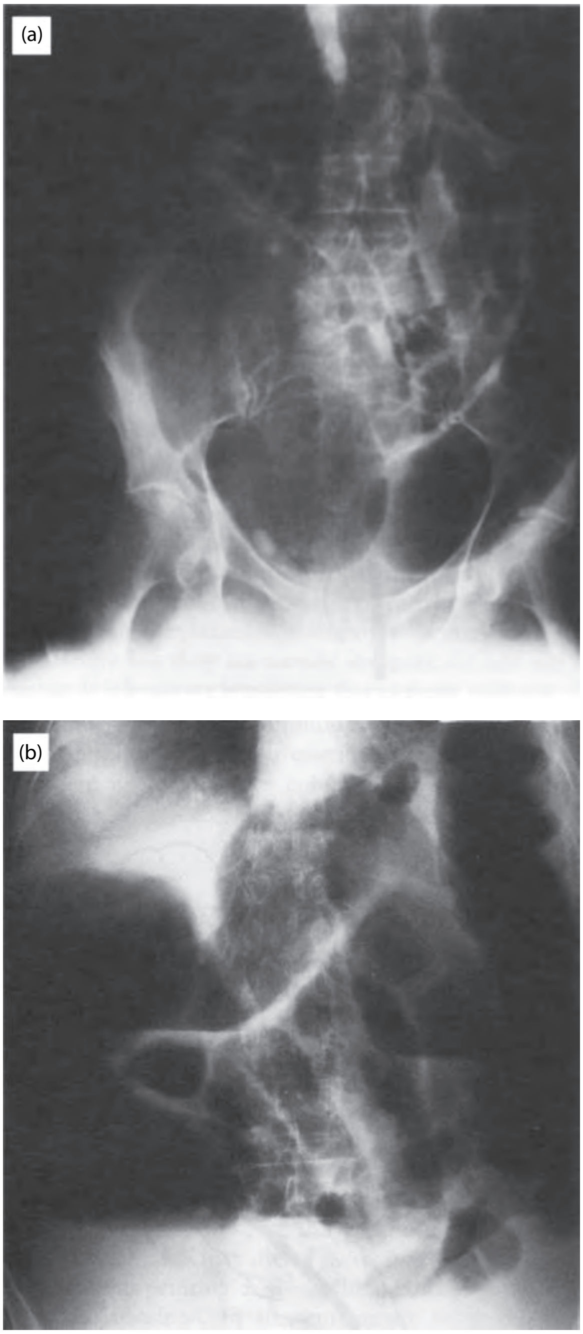

Figure 30.10 Plain abdominal radiographs showing large bowel obstruction: (a) supine film, (b) erect film, showing a fluid level in the caecum.

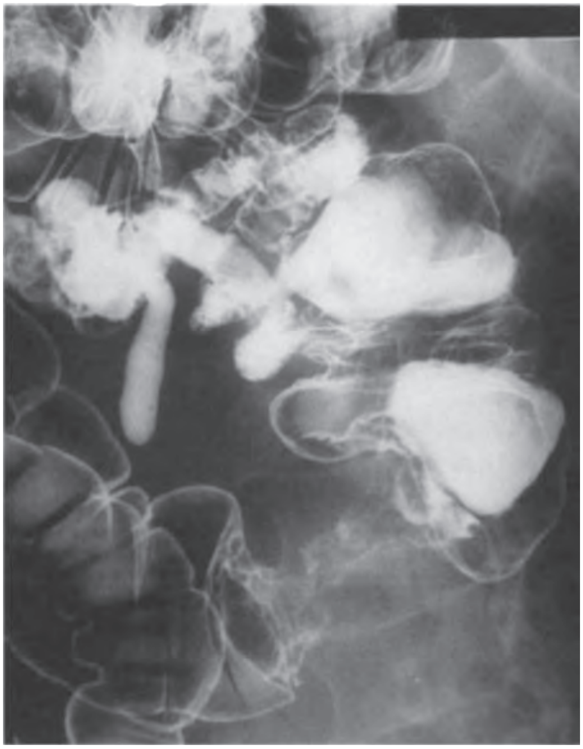

Figure 30.11 Barium enema appearances of a colonic cancer with typical 'apple core' shouldering.

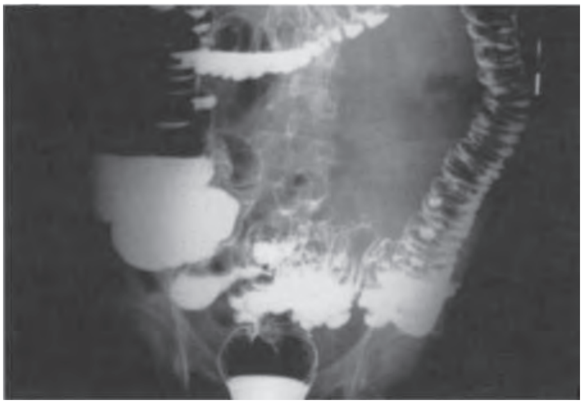

Figure 30.12 Severe sigmoid diverticular disease on barium enema. In this instance a carcinoma was missed.

Strictures in the presence of diverticular disease are particularly difficult to interpret and may require direct endoscopic visualization and biopsy. Small polyps may be missed on barium enema and conversely diverticula or small particles of faecal matter may be misinterpreted as polyps. It should be stressed that both barium enema and colonoscopy are highly operator dependent and both can miss quite significant lesions. Thus in the patient who presents a diagnostic dilemma it may be quite justifiable to use both investigations.

Complications of barium enema

Serious complications are extremely rare. The incidence of perforation is approximately one in 25 000. When it occurs it is usually associated with passage of the rectal tube and it may occur proximal to a colostomy. Very occasionally perforation may result from preparation of obstructed bowel using a stimulant laxative such as Picolax.

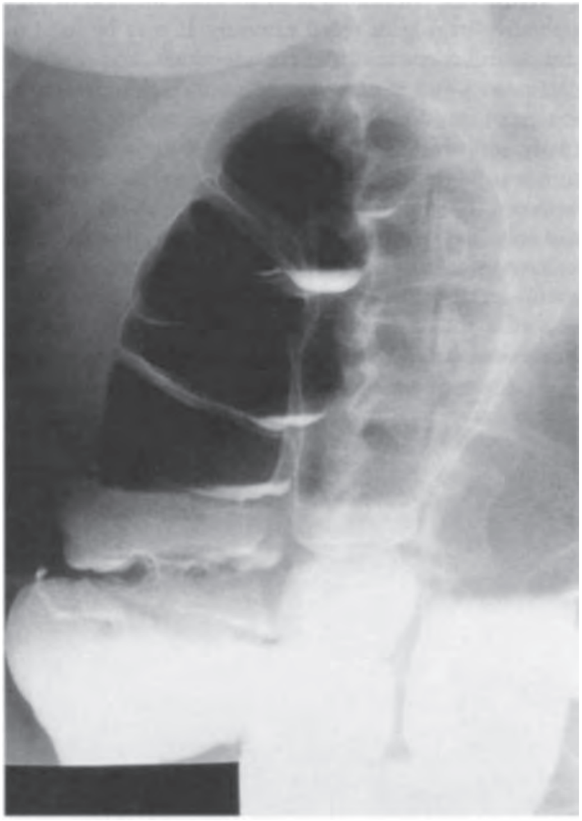

Figure 30.13 Spasm in the caecum interpreted as a stricture on barium enema.

Peroral enema

This technique is sometimes helpful where a standard barium enema has been unsuccessful in demonstrating the caecum. Barium is given by mouth and is monitored by fluoroscopy until it has reached the transverse colon. At this stage air is insufflated per rectum and the right colon is examined. Antispasmodics such as Buscopan may be useful in relaxing the colon for this examination.

Water-soluble enema

If there is a danger of barium entering the peritoneal cavity or if the bowel is obstructed then a water-soluble enema is a useful alternative to a barium. Gastrograffin or Niopam is frequently used. Indications for a water-soluble contrast enema include a suspected anastomotic leak, suspected perforation from or to exclude a pseudo-obstruction. Barium is avoided in the obstructed patient as the study may be followed by immediate surgery which may be compromised by the presence of barium in the colon.

Radio-opaque markers

In order to measure colonic transit radio-opaque markers can be used. Twenty markers are swallowed and in the normal individual the single abdominal radiograph taken on day 5 will show that at least 14 (80%) have been passed. For more detailed information daily radiographs can be taken, or 20 markers of different shapes can be ingested daily on three consecutive days and a single radiograph taken on day 4. In normal individuals the mean total colonic transit time is 30 hours in males and 38 hours in females.

Colonic scintigraphy

Instead of radio-opaque markers it is possible to use material labelled with radioisotopes, e.g. ^{131}I bound to cellulose or indium-^{111} DTPA. The isotope is ingested and the abdomen scanned using a gamma-camera at 6, 24, 48, 72 and 96 hours.

Radiolabelled leucocyte scanning

Intravenous injection of autologous leucocytes labelled with indium-111 can be used to detect active colitis. The leucocytes accumulate in the inflamed mucosa and this relatively non-invasive procedure is useful in assessing the activity and extent of ulcerative colitis and Crohn's colitis. Technetium is an alternative to indium for labelling leucocytes.

Ultrasound

Abdominal ultrasound is widely used for the detection of hepatic metastases both preoperatively and in follow-up for patients with colorectal cancer. It can also be used for the elucidation of abdominal masses and primary colorectal cancers have a characteristic ultrasound appearance. It is not, however, reliable enough to use as a standard investigative technique in a patient suspected to have the disease. Intraoperative contact ultrasound (Figure 30.14) can be used to screen the liver for metastatic disease and indeed this is the most sensitive available method for picking up hepatic deposits (Figure 30.15).

Transrectal ultrasound is an accurate method of preoperative staging of rectal tumours. It may be used to distinguish between benign adenomas and invasive carcinomas and it may also be used to determine the extent of invasion through the bowel wall. It is particularly sensitive in distinguishing between T2 and T3 tumours but not quite so sensitive at distinguishing between T1 and T2 tumours (Figure 30.16). Unfortunately, its sensitivity for picking up lymph node metastases in the perirectal tissues is poor. The most useful rectal probe operates at 7 or 10 MHz and consists of a rotating probe inside a water-filled balloon which can be distended within the rectum to achieve contact between the ultrasound probe and the rectal wall (Figure 30.17).

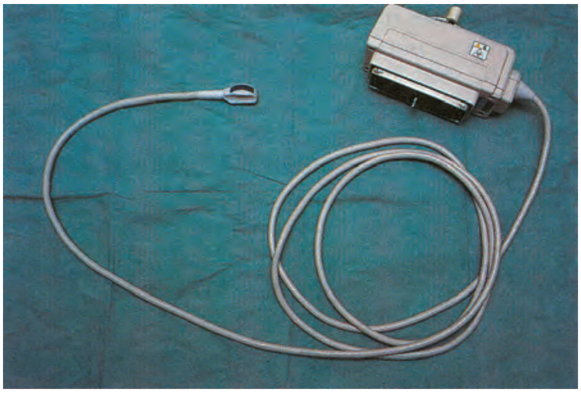

Figure 30.14 Intraoperative ultrasound probe.

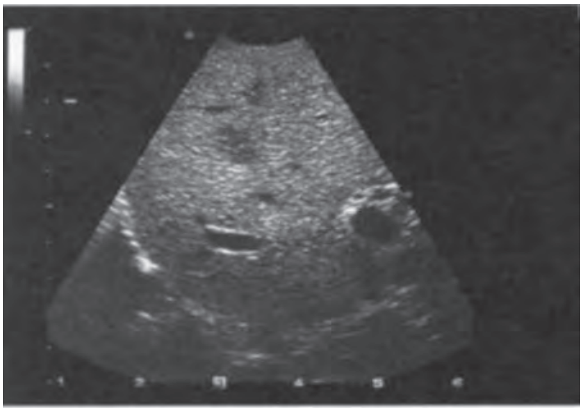

Figure 30.15 Ultrasound appearance of hepatic metastases – image obtained at intraoperative contact ultrasound.

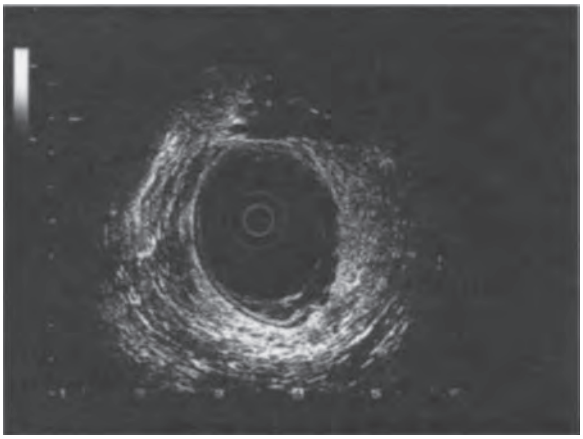

Figure 30.16 Transrectal ultrasound appearance of a rectal tumour. This is a T2 tumour showing breaching of the muscularis propria.

CT scanning

CT scanning is widely used for preoperative staging especially of rectal cancer. It has advantages over ultrasound in that its sensitivity for liver metastases (Figure 30.18) is higher, and an image of the primary tumour in the pelvis can be obtained (Figure 30.19). Again CT can also be used to diagnose abdominal masses and it is of particular value in elderly patients where barium enema and colonoscopy are impractical because of the patients' inability to retain either contrast or air.

A recent development has been virtual colonoscopy where the dataset acquired from a helical CT scan of the abdomen can be reconstructed in order to provide a 'fly through' view of the inside of the colon (Figure 30.20). This procedure shows great promise but like barium enema and colonoscopy it requires full bowel preparation and insufflation of air or CO_2. In addition, because of pooling of liquid in the colon, the CT has to be repeated once with the patient lying prone and again with the patient lying supine. Virtual colonoscopy has been quite widely studied but as yet it has not been shown to be more

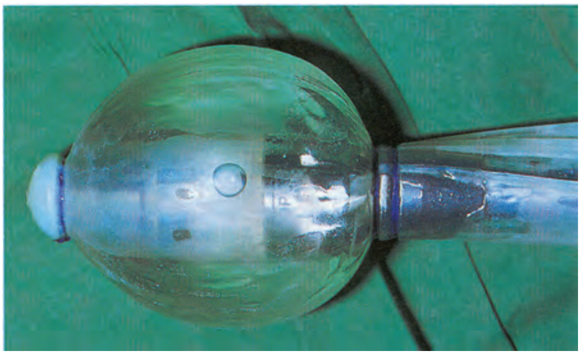

Figure 30.17 Head of a rectal ultrasound probe with the balloon inflated to ensure contact with the rectal wall.

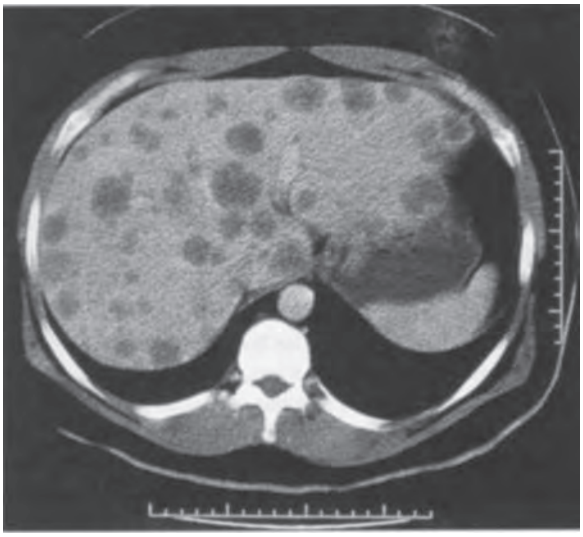

Figure 30.18 CT scan showing multiple hepatic metastases.

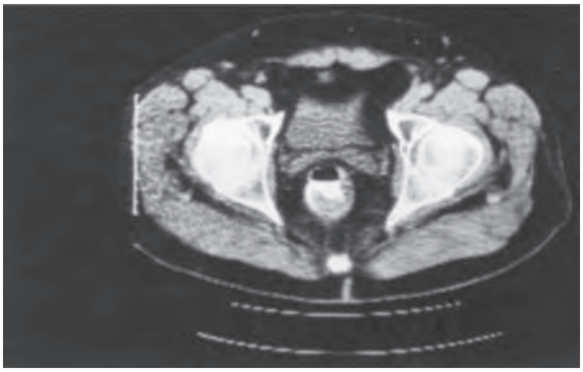

Figure 30.19 CT of rectal cancer showing posterior operable tumour.

sensitive or specific than either a high-quality barium enema or colonoscopy. However, future developments may lead to this technique being able to discriminate malignant lesions from non-malignant lesions with a high degree of accuracy.

MRI scanning

Because of the slow image acquisition time MRI scanning has not supplanted the much more rapid helical CT scanning. However, it does provide particularly good images of the rectum and the latest 1.5T machines with pelvic coils provide very high-definition pictures of the rectum and the mesorectum which has improved preoperative staging considerably (Figure 30.21).

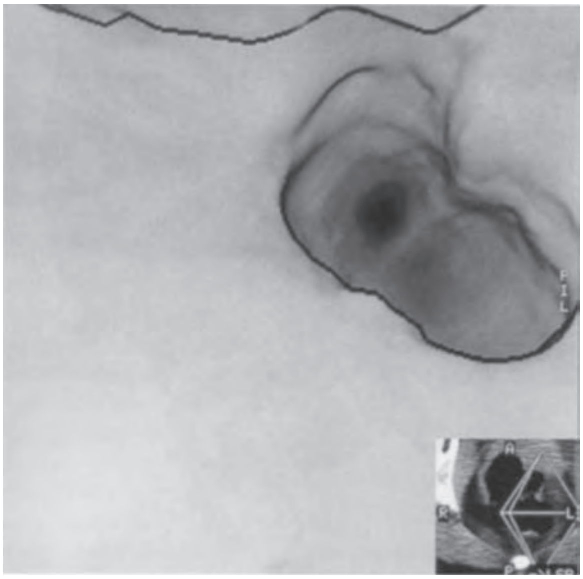

Figure 30.20 CT colography ('virtual colonoscopy').

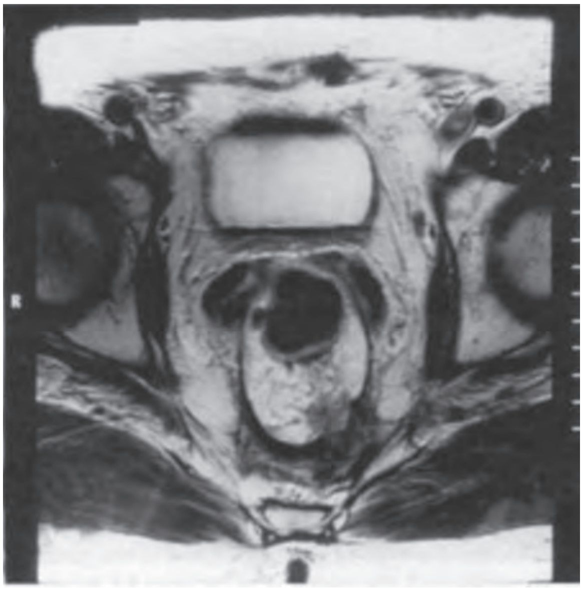

Figure 30.21 MRI of the rectum obtained using phased array pelvic coils.

Functional disorders of the large bowel and pelvic floor

The pelvic floor comprises all the structures that close and support the bottom of the pelvis. These structures provide both dynamic and static support via musculofascial components, enabling it to support, sustain and regulate the canals running through its hiatus. These include the urethra, anal canal and vagina in females, with these organ systems functioning interactively with the supporting pelvic floor.

Gross anatomy

Just inferior to the abdominal cavity and its structures lies the bony pelvic ring, with the levator ani muscles running across this space. The bony borders to this opening traversed by the pelvic floor are the pubic bones anteriorly, ischial spines laterally and the sacrum posteriorly.

In practical terms, the pelvic floor is synonymous with the levator ani because this muscle forms the effective contractile support structure of the region. This muscle takes the form of a broad thin sheet that attaches anteriorly to the posterior surface of the body of the pubis, and is suspended laterally from the pelvic wall to the ischial spines and coccyx, which lie posteriorly. The part of the muscle that attaches to the pubis forms the medial portion of these fibres, and from the pubis this attaches to the perineal body behind the prostate to form the levator prostate. In the female, these medial fibres attach to the lateral vaginal wall to form the pubovaginalis. Other fibres from the pubis pass behind the anorectal flexure, where they fuse with the deep part of the external anal sphincter (EAS) to form the puborectalis. The fibres running from the pubis, together with the fascia covering obturator internus, form the pubococcygeus. The part of the levator ani arising from the lateral wall of the pelvis posterior to the ischial spine is known as the iliococcygeus. Pubococcygeus and iliococcygeus merge imperceptibly with each other as a continuous sheet of muscle. The levator musculature provides support to all the pelvic floor organs and is traversed by the urethra, vagina (in women) and anus.

All the components of the levator collectively contribute to maintaining the position of the pelvic viscera. In females, contraction of the levator ani and its attachments results in the anterior movement of vagina and ESA anteriorly towards the pubic symphysis. On contraction of the pelvic floor, this anterior movement produces occlusive forces on the urethra and rectum, thus contributing to dynamic support of these organs and hence continence. Because the levator muscle complex provides support to all three organ systems (urethra, vagina and anus), its weakness will result in impaired function of any or all of the structures being supported. Muscular dysfunction can result from stretch or tear injuries to the pelvic floor muscles; however, the most common aetiology for muscular dysfunction is a denervation injury from childbirth. Injury to the pudendal nerve can result in dysfunction of the urethral sphincter, anal sphincter, and motor or sensory dysfunction of the perineum. Significant damage to pudendal innervation can result in multisystem dysfunction, causing prolapse and combined mixed incontinence.

Numerous epidemiological studies link pelvic floor disorders with parity. Damage to nerve, muscle and connective tissue may occur after vaginal delivery, all of which may contribute to pelvic floor disorders. With increasing age, latent injuries from vaginal deliveries may manifest as continence disorders, difficulty with urination and bowel motions, and pelvic organ prolapse. Surgery may be a potential curative option, provided the right diagnostic strategies are initially followed. Care must be taken as pathology is often multifactorial, and restoration of anatomy may not always provide positive short- and long-term functional outcomes.

Epidemiology of pelvic floor-related bowel dysfunction

These disorders include several different clinical problems such as faecal incontinence, constipation and prolapse of the rectum. They are often complex and can involve the functions of smooth and skeletal muscles, their nerves and connective tissues. Aetiology can be post-traumatic (anorectal surgery, difficult vaginal deliveries), or from chronic evacuation difficulties. Many cases can be idiopathic.

Epidemiology of faecal incontinence

The true prevalence of the problem varies in every country. Faecal incontinence is frequently underestimated because of the embarrassment and reluctance of patients to discuss the condition, and varying levels of coping. The incidence of faecal incontinence ranges between 0.5% to 5% in most studies. It is higher in institutionalized individuals – around 30% in elderly people and 50% in patients with neuropsychiatric disorders. Gender also plays a significant role. Over the age of 45, women are nine times more likely to suffer with faecal incontinence than men of the same age. This increased risk may be attributable to obstetric injury, which is likely to be the most important aetiological factor in women. Other risk factors for faecal incontinence include diabetes, irritable bowel syndrome (IBS) and anorectal surgery.

Despite traumatic childbirths, which may lead to unidentified sphincter defects, only a minority of women ever become symptomatic early on. These patients may however become symptomatic later in life or with subsequent vaginal deliveries. A varying number of these women will also have sustained pudendal nerve injuries, which may manifest in different ways. The incidence of sphincter injury is significantly higher in patients with perineal tears. Menopause and ageing is also noted to be a risk factor for the development of altered continence. The prevalence of faecal incontinence in women 75 years and older is between 9% and 17% – significantly higher than the general population.

Epidemiology of evacuatory disorders

Constipation is one of the most common complaints of patients seeing their GPs or colorectal surgeon. The prevalence of chronic constipation can range from 5% to 35%. This can be caused by several aetiologies. Obstruction of the pelvic outlet, often known as obstructed defecation syndrome (ODS), is a common cause of constipation and is attributable to muscular dysfunction of the pelvic floor. In a population study performed by Talley *et al*, the prevalence of this condition was 16.5% in women and 5.2% in men. There was a significant increase in prevalence of this form of evacuatory disorder with age.

Multiple risk factors are associated with ODS. Constipation in youth to middle age is approximately three times greater in women, and the prevalence increases in men and women with age. Laxative and enema abuse have also been associated with ODS.

Rectal prolapse

Rectal prolapse occurs when the full thickness of the rectal wall protrudes through the anus. It is the most common type of distal gastrointestinal tract prolapse. If only the mucosa of the rectal wall protrudes through the anus, this is termed a mucosal prolapse. By contrast, full or partial thickness prolapse can also occur in the rectum but not pass beyond the anus. This is termed internal intussusception. The true incidence of rectal prolapse is not known because of under-reporting. It is associated with longstanding constipation, chronic straining, pregnancy, anorectal surgery, female gender, ageing, neurological disease (such as dementia) and mental illness.

Diagnostic modalities in pelvic floor disease

Pelvic floor disease comprises numerous clinical manifestations, depending on the precise nature and combination of pathology of the local anatomy and function. In order to accurately diagnose these disorders, a number of radiological techniques are utilized to assess structure and function, statically and dynamically. In assessing patients, there is general recognition that the majority of them have a multiplicity of pelvic floor and perineal soft-tissue abnormalities across compartments. Dynamic imaging modalities are therefore required to define the real-time integration of these anomalies and to highlight their significance in each case, particularly where there is clinical or radiographic evidence of a dominant pathology and where corrective surgery is contemplated.

Ultrasound scanning, X-ray dynamic contrast radiography and MRI form the mainstay of anatomic and functional assessment. Transperineal ultrasound can be used to assess the component parts of the anterior, middle and posterior pelvic compartments to define their interaction during straining and simulated defecation in patients with symptoms of evacuatory difficulty.

Pelvic ultrasound

Ultrasonography of the pelvic floor has assumed a central role in the diagnostic work-up of pelvic prolapse syndromes, obstructive defecation and faecal incontinence. It can be a useful first-line imaging approach as it helps discriminate patients with anatomical abnormalities who are likely to benefit from surgery and those requiring conservative management. More recently, dynamic anorectal ultrasonography and MRI have been used successfully in evaluating these disorders. Introital ultrasound and, more importantly, endoanal ultrasound have become accepted approaches for assessing anal sphincter pathology.

Pelvic MRI

MRI has an important role in analysing the pelvic floor musculature. In the supine position, the pelvic floor is dome shaped at rest. During voluntary contracture, the levator straightens out and becomes more horizontal. While bearing down, the muscles descend a variable amount and become basin shaped, with widening of the genital hiatus. MRI has previously shown inward movement of the levator on contraction and outward movement with straining. MRI scanning of the levator ani can assist in the recognition of asymmetry between the two sides, demonstration of the relationship with the obturator internus muscle, visualization of defects and, if the appropriate images are taken, determination of muscle volume.

Dynamic contrast proctography

Dynamic contrast proctography (henceforth referred to as defecating proctography) has traditionally been used for investigating intraluminal anorectal abnormalities, with well - established criteria for diagnosing rectal prolapse and intussusception. In its classic description, mucous prolapse is defined as a rectal wall infolding <3 mm thick confined to the anterior or posterior margin, which does not show a tendency to migrate distally on straining. Conversely, a circumferential infolding of the rectal wall <3 mm that descends toward the anal canal is defined as intussusception. This is described as intrarectal when it remains within the rectum and intra-anal if its apex penetrates the anal canal. Defecating proctography can determine morphological features such as thickness, depth of descent and the point of inversion from the anal verge.

In addition, intussusception can be graded by using a three-point scale, depending on the involved rectal wall appearance at the end of evacuation:

- grade 1 intussusception is a 3–5 mm thick intraluminal filling defect that has a mucosal component only
- grade 2 is 5–10 mm thick and includes both mucosal and mural components
- grade 3 or full-thickness intussusception is assumed if the prolapsed folds are thicker than 10 mm, penetrate the anal canal and appear to impede the expulsion of rectal content.

A complete external rectal prolapse is diagnosed when the entire thickness of the rectal wall is extruded through the anal canal. This can be reducible or irreducible.

A rectocele appears as any rectal protrusion anterior to a line extending upward through the anal canal (Figure 30.22). Its depth, either at rest or on straining, should be measured as the shortest distance from the deepest margin of where it actually reaches the anterior rectal wall and the expected line mentioned above. Rectoceles measuring <2 cm deep are graded as small, moderate if measuring 2–4 cm, and large if >4 cm. With the introduction of open-configuration MRI scanners, image acquisition in the vertical or even sitting position is now possible and provides a global view and analysis of the musculature, pelvic viscera, anorectal angle, pelvic floor muscle function and pelvic floor descent. With this technique the rectal wall is seen even more clearly, making intussusception and rectocele evaluation even more reliable. Dynamic MRI has been found to be at least equivalent to conventional defecography in all aspects tested. This technique has the advantage of showing sphincter function and global motility of the pelvic floor while avoiding radiation exposure, constituting a significant aid to surgical and therapeutic planning.

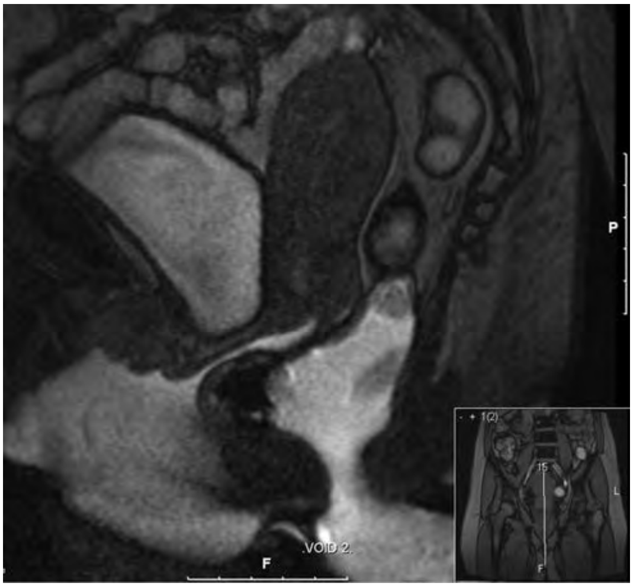

Figure 30.22 Magnetic resonance defecating proctogram showing pelvic floor descent and rectocele.

Endoanal ultrasound vs endoanal MRI

Anal incontinence is a complex and debilitating condition producing considerable morbidity in those affected. Faecal continence depends on intact function of the anorectal sphincter, appropriate consistency of faeces and maintenance of higher mental function.

Anorectal sphincter function may be impaired by disruption of the EAS or internal anal sphincter (IAS), atrophy of the anorectal sphincter mechanism or a combination of all three. Disruption of the EAS occurring during vaginal delivery is the most common traumatic cause of anal incontinence. IAS disruption is less common after local trauma, most commonly as a result of surgery. Isolated disruption of the IAS is not seen after childbirth but often occurs combined with external sphincter damage. Sphincter atrophy is generally related to pudendal neuropathy often presenting as delayed-onset incontinence. Along with functional assessment, anatomical assessment of the anorectal sphincter as well as accurate description of the site and cause of sphincter disruption are fundamental to patient management.

Endoanal ultrasound and endoanal MRI are the principal imaging modalities employed to make an anatomical assessment of the anorectal sphincter. Studies in healthy volunteers have demonstrated the relative merits of each technique. Endoanal ultrasound performed with the patient prone or in the left lateral position using a 7 MHz or 10 MHz rotating transducer allows 360° visualization of the anal canal. Endoanal ultrasound is widely available and provides excellent visualization of the IAS enabling the focal defects and thinning to be detected. Incomplete visualization of the external sphincter, difficulty in distinguishing pathological defects from the normal asymmetry, reliance on operator dependence and poor interobserver variation have been cited as limitations of the technique. Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal-to-noise ratio, resulting in high spatial resolution images. However, the limited availability of endoanal coils outside specialist units has resulted in less widespread familiarity with this technique. Endoanal MRI allows the comprehensive assessment of atrophy and focal defects of the external canal; however, the internal sphincter is less well defined. Several studies comparing the diagnostic accuracy of endoanal ultrasound and endoanal MRI have been performed. The cohorts are generally small. The use of surgery as the diagnostic 'gold standard' results in the over - representation of patients with disruption of the EAS, as these alone are candidates for surgical repair. Local practice and expertise is often reflected in the findings of these single - centre studies.

Magnetic resonance defecography

Defecography is one of the most important examinations to be performed in patients with pelvic floor dysfunction. It can provide dynamic and static images of pelvic floor structures during rest, squeeze and evacuation. The examination depends on voluntary control of the pelvic floor and passive emptying of the rectum.

Defecography is the dynamic study of evacuation. Wallden was the first to investigate the relationship between changes in pelvic dynamics, rectocele, enterocele and symptoms of obstructed defecation. Defecography allows a closer physiological evaluation of the evacuation process than other diagnostic tools. It also provides measurements in the resting, squeeze and bearing-down positions to show both anatomic and physiological abnormalities. Defecography may be indicated in patients with chronic constipation to evaluate obstructed defecation, which can be the result of rectocele, sigmoidocele, enterocele, internal mucosal intussusception, anismus and increased perineal descent. Treatment should still be planned in combination with patient symptoms. Performing this study by MRI is an accurate method for evaluating morphology and function of anorectal and pelvic muscles and organs. The dynamics of the pelvic floor may be evaluated in multiple compartments in high-resolution images and video (dynamic) mode.

Unlike earlier forms of imaging such as conventional X-ray cinedefecography, MRI makes it possible to view the pelvic floor in its entirety and in multiple compartments both at rest and dynamically, thus providing information essential for surgical planning and choice of treatment approach. With MRI, the opening of the anal canal and the anorectal angle can be evaluated during sphincter contraction and evacuation, and the elimination of endorectal contrast quantified. The rectal walls can also be clearly observed, and disorders such as intussusception and rectocele may be identified. In addition, it is possible to view the descent of anterior, mid- and posterior compartments of the pelvis. With the addition of an endorectal or endoanal coil, the structure of the anal sphincters may also be assessed. MRI can be performed in the upright or sitting position utilizing an open-configuration system. This has the advantage of simulating the physiological position of defecation, while sacrificing spatial resolution due to necessary attenuation of the MR signal with the open magnet.

Defecography with MRI provides accurate evaluation of the morphology and function of the anorectal and pelvic muscles and organs involved in pelvic floor dynamics. The spatial resolution is high enough to view the relevant morphological structures and dynamics of the pelvic floor, demonstrating relevant pathologies affecting the defecatory mechanism.

Anorectal manometry

Functional anorectal manometry (ARM) testing was developed during the early 1960s. ARM allows a better understanding of the physiology of continence and defecation, with a clearly defined role in the diagnostic work-up of diseases of the pelvic floor.

The anal canal is a narrow passage measuring 2–5 cm long, which is normally closed by the IAS and EAS. The IAS is smooth muscle, maintaining approximately 80% of resting anal tone, whereas the EAS, a striated muscle, is responsible for the remainder. The puborectalis muscle, a U-shaped component of the levator ani complex, blends with the upper end of the EAS and maintains an acute rectoanal angle at rest. Rectal distension evokes involuntary relaxation of the IAS and increases rectal contractility, thereby inducing the desire to defecate. If convenient, defecation is then initiated by relaxation of the anal sphincters and pelvic floor muscles. Conversely if inconvenient, the rectum can relax to accommodate stool, with the sense of urgency subsiding. The EAS and pelvic floor muscles, being striated muscles, can be contracted voluntarily to preserve faecal continence. ARM requires a catheter (which comes into direct contact with the patient), pressure transducers, a recording system to store the digitized signals and software to analyse the recordings.

Multichannel water-perfused catheters used to be the most common tools for performing anal manometry. These have lately been replaced by solid-state or air-charged catheters, which are considerably easier to manage and maintain. Measurements can be performed as a continuous pull-through, or at set levels within the anal canal (station pull-through). The continuous pull-through technique requires the catheter to be withdrawn at a continuous speed from the anal canal, which can provide a detailed recording of pressure profiles, and computer-based three-dimensional representations of the anal canal. With the widespread availability and ease of use of endoanal ultrasound, station pull-through has become more common, with anal canal pressure measurements performed at 1 cm increments in the anal canal. This method provides a more accurate assessment of anal pressures since there is a stabilization period between each reading, thereby reducing artefact. This is the method that the authors perform, with the catheter tip placed 5 cm cephalad from the anal verge. Anal pressure measurements are then taken at 1 cm intervals after a stabilization period of 10–20 seconds. Rest and squeeze pressure are recorded at each centimetre up to 1 cm from the anal verge. Anal pressures, capacity, sensation and rectoanal inhibitory reflex are tested. The rectoanal inhibitory reflex is thought to be central to the 'sampling effect' of the rectum. Rectal distension with small volumes should cause a contraction of the EAS followed by a pronounced IAS relaxation. This reflex is absent or diminished in patients with Hirschsprung disease.

The mean resting pressure in healthy volunteers ranges from 40 to 70 mmHg. The IAS generates around 60% of resting pressure, with the external sphincter and surrounding soft tissue contributing the remaining 40%. Maximal squeeze pressure in healthy individuals should be between two and three times baseline resting value. The EAS is the main contributor to these pressures. Anal resting and squeeze pressures are frequently reduced in faecal incontinence. Among patients with weak or normal anal pressures, other factors such as diarrhoea and disturbances of rectal compliance/sensation may also contribute to faecal incontinence. ARM can also be useful to discriminate defecatory disorders from other causes of chronic constipation. The rectal balloon expulsion test for example is a useful screening test for a functional defecation disorder. Features of evacuation disorders on ARM include impaired relaxation or paradoxical contraction of the anal sphincter (i.e. anismus) or inadequate increase of rectal pressure during simulated evacuation. Anal resting tone may be increased in patients with a functional defecation disorder, as well as in patients with anal fissures.

Colonic transit studies

These are commonly performed with a radioactive marker or radio-opaque capsules (Figure 30.23), commonly known as a Sitzmark test. This test is often useful in patients who are otherwise well, but suffer with chronic constipation refractory to medical management. The test allows a clinician to differentiate between normal transit and slow transit constipation. In this procedure, the Sitzmark capsule is ingested, and abdominal radiography performed 5 days following its administration (Figure 30.24). In normal controls, most markers are eliminated by day 5. If more than 20% of the markers remain in an equally scattered fashion, then slow transit constipation exists. If the markers are confined to a particular area of the colon, this may imply some form of obstruction at that point, which needs further investigation. If no obstruction is found, more detailed radioactive marker - based assessment with multiple abdominal radiographs over

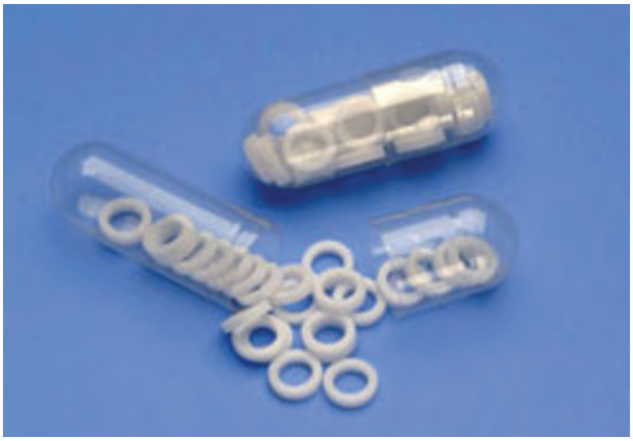

Figure 30.23 Sitzmark capsules.

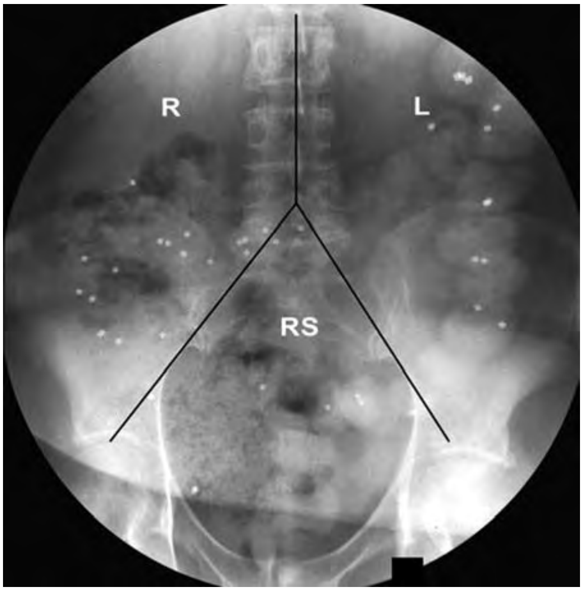

Figure 30.24 Sitzmark's test with markers in the right hemicolon (R), left hemicolon (L) and rectosigmoid (RS).

time may need to be performed, in order to better define the affected segment of colon.

Functional manifestations of pelvic floor disease

Pelvic floor disease can manifest in a number of ways. This can comprise both functional and anatomical pathology, resulting in disorders of urinary function, faecal function and pelvic organ position. Varying studies have been performed to provide a better understanding of the coexistence of urinary, faecal and genital symptoms. There is a high incidence of coexistence of incontinence and genital prolapse. In patients seen with faecal incontinence, 20–55% also complained of urinary incontinence, with 7–20% also complaining of genital prolapse. Conversely, of patients presenting with rectal prolapse, over 60% also complained of urinary disturbance and 30% of genital prolapse. The frequent coexistence of urinary and colorectal dysfunction indicates the need for a multidisciplinary approach to the evaluation of patients with these conditions.

Urinary incontinence

Urinary incontinence is the involuntary loss of urine. Stress urinary incontinence is the involuntary loss of urine that occurs during physical activity such as coughing, sneezing, laughing or exercise. It is a distressing problem of bladder storage in which the strength of the urethral sphincter is diminished and unable to prevent urine flow when there is increased abdominal pressure. This is often, but not exclusively, the result of weakness of pelvic floor support with resulting rotational descent of the bladder neck and proximal urethra during increases in intra-abdominal pressure. Urge incontinence is the sudden involuntary contraction of the bladder causing an immediate unstoppable urge to urinate. Urinary incontinence can be of the stress, urge or mixed variety. Epidemiological studies have estimated prevalence rates of between 10% and 40%. The EPICONT study in Norway, which involved over 20 000 women, noted a gradual increase in prevalence until age 50, when it seems to plateau at about 30%, rising again at age 70.

Faecal incontinence

Faecal incontinence is the involuntary or inappropriate passage of flatus, liquid or solid stool that is a crucial and hygienic problem. Similarly to urinary incontinence, this can be stress, urge or mixed incontinence. In addition, incontinence can also be passive, occurring without one's knowledge. The pathological basis of faecal incontinence can be muscular, neurogenic or idiopathic. Patients may have a decrease in sensory acuity in the anal canal at the anal margins. Often the patient cannot distinguish between the presence of flatus or faeces in the anorectum. This prevents the normal sampling reflex from working appropriately, resulting in, initially, involuntary loss of flatus and liquid stool, progressing to incontinence of formed stool. Faecal incontinence is often underestimated because of the embarrassment and reluctance of patients to discuss this condition. The social stigma and embarrassment of being incontinent of faeces can lead people to severely limit their activity. Incontinence of stool or flatus occurs at least weekly in 2% of adults. This rate may be higher in women, especially in those with obstetric-related structural sphincter damage. With increasing age, prevalence of faecal incontinence also rises, which may reflect degenerative changes of the sphincter mechanism over time. The consequences of faecal incontinence on a patient's quality of life may be substantial. Loss of self-esteem, difficulty travelling or maintaining employment, and strain on personal relationships may adversely affect patients and their families, with economic consequences borne by individual and state.

Pathophysiology of faecal incontinence

Normal defecation and continence require a complex interplay of several important factors. The rectum, which functions as the organ of storage, requires appropriate distensibility, compliance and sensory ability. The passive musculature which maintains continence should be of sufficient calibre and contractility, providing an adequate resting pressure to hold back stool in the rectum. The voluntary muscles should also be of normal length and thickness and contract appropriately, maintaining an acute anorectal angle, so that the faecal bolus is supported over the levator muscle and not directly over the anal canal. The outflow system should be intact, and stool transit time should also be within normal range.

Denervation has been found in the pelvic floor muscles of patients with constipation and defecation disorders that cause excessive straining. These patients often show the physical sign of perineal descent. The terminal portion of the pudendal nerve in an adult is approximately 9 cm. In patients with abnormal descent of 2–3 cm, a stretching force to the distal nerve of 20–30% is therefore exerted. Stretching of these nerves during straining may lead to secondary neuropathic damage with consequent pudendal neuropathy.

Patients complaining of faecal incontinence typically present in one of two ways. They may have a significant obstetric history with prolonged labour, instrumental delivery and sphincter injury. Injuries may have been occult and never treated, or surgically repaired either at presentation or in a delayed fashion. The other presentation is a patient with years of forceful straining at defecation. Patients may be aware of the urge to defecate, but are unable to defer or prevent the passage of faeces. On the other hand, patients may complain of leakage in a passive fashion, with faecal incontinence occurring while asleep or unawares.

Management of faecal incontinence

Management of faecal incontinence is primarily by conservative means, including dietary and lifestyle changes, antidiarrhoeal medication, biofeedback therapy, absorbent pads and anal plugs. Surgical options include sphincteroplasty, postanal repair and, more recently, sacral nerve stimulation (SNS). SNS is a minimally invasive technique that allows modulation of the nerves, and therefore muscles, of the pelvic floor. It is achieved via the application of an electrical current to a sacral nerve by insertion of an electrode through the corresponding sacral foramen (Figure 30.25). Sacral nerve stimulators were first implanted in 1981 for the treatment of urinary urge incontinence, with SNS first used for the treatment of faecal incontinence in 1995. In its current form, SNS involves extradural stimulation within the sacral canal, which has reduced complications compared with previous transcutaneous, transvaginal and transrectal techniques. SNS involves a testing phase known as peripheral nerve evaluation (PNE). PNE determines the feasibility of electrode implantation into the sacral foramina, followed by a 2–3 week period of stimulation with a temporary electrode to assess the potential benefits of SNS. This allows identification of patients who are likely to have a positive response to SNS, into whom a permanent electrode can be inserted.

Recent studies and meta-analyses (Table 30.1) have shown SNS to be a safe and highly effective treatment for faecal incontinence, improving both functional and quality of life outcomes in patients where maximal conservative therapy has failed. There is generally an increase in both resting and squeeze pressures following successful SNS implantation, although the significance of this is unclear. The resultant improvement in continence may be from an augmentation action on the sphincter complex and puborectalis, as well as modification of afferent and efferent neurological pathways in bladder and bowel function. SNS influences rectal sensory function, with patients demonstrating increased rectal sensitivity to balloon distension testing. This improved sensation may contribute to an increased awareness of rectal content and hence continence. SNS has also been shown to be effective in unifocal as well as multifocal sphincteric defects.

Max tolerable volume (mL)	20	406	334	-5.33

FIQL, faecal incontinence quality of life; WMD, weighted mean difference.

As well as its benefits vs conservative treatments, SNS has been demonstrated to be cost effective and less morbid relative to other surgical interventions, including the artificial bowel sphincter, dynamic graciloplasty and end stoma.

Disorders of defecation

This group of disorders is often described as constipation by patients. Constipation, with its associated symptoms, is a common bowel problem. Constipation itself is a misleading name as it does not necessarily mean the passage of hard or infrequent stools. It can also mean excess defecatory strain, or passage of stools that are too small/hard, described as 'rabbit pellets'. The most common symptoms associated with constipation are a feeling of having to strain at stool, abdominal pain or bloating, and dissatisfaction or a feeling of incomplete rectal emptying after passing stool.

The causes of constipation can be varied and multifactorial, being a symptom of organic disease of the gastrointestinal tract. Patients with constipation can be divided into two main groups – those with intestinal dysmotility/impaired transit and those with outlet obstruction. Broadly, the causes can be categorized as (1) systemic factors that affect normal colonic and rectal function, (2) primary colonic and anorectal factors and (3) psychological factors.

ODS is a common entity among the disorders of defecation. It is under-reported, estimated to affect between 15% and 20% of the adult female population. This subset of patients may respond well to surgical management. Known anatomic findings associated with ODS include rectocele and rectal intussusception. It is this redundancy of the distal rectum that has been shown to be amenable to surgical resection with restoration of normal rectal anatomy and resolution of symptoms. Patients with ODS may also suffer with anismus, otherwise known as paradoxical puborectalis contraction, which manifests as a failure of the puborectalis muscle to relax and open the rectal angle necessary for smooth defecation.

Hypothyroidism, diabetes, hypercalcaemia, connective tissue disorders such as scleroderma and amyloidosis can all contribute to constipation. Neurological disease, congenital or acquired, may also be associated. In addition, many drugs cause constipation as a side effect, and most drugs aggravate constipation in some patients. These may include opiate-based analgesics, anticholinergics, antidepressants, beta-blockers, calcium antagonists and diuretics.

Surgical management of obstructed defecation syndrome

Stapled transanal resection of the rectum (STARR) has been proposed by Longo for the treatment of ODS. It involves a double-stapling technique performed transanally to produce a transanal full-thickness rectal resection with the goal of correcting structural/anatomical abnormalities associated with ODS, leading to restoration of rectal flow, normal rectal wall thickness and compliance, correction of rectocele, and correction of rectal intussusceptions. It has been performed for over 6 years now, and numerous publications have demonstrated the safety and efficacy of the procedure in the short–medium term. Rectoceles themselves can of course be treated transvaginally in women to good effect, but there are concerns about long-term efficacy, dyspareunia and wound problems. The European STARR registry, established in 2008, has tracked over 3000 patients who have had the procedure, with good effects maintained at 12 months of follow-up. Complications were reported in 36%, with the majority complaining of urgency, followed by bleeding, septic events, staple line complications and incontinence.

Rectal prolapse

The definition of rectal prolapse is the protrusion of the full thickness of the rectal wall through the anus (Figure 30.26). This protrusion differs from mucosal prolapse and internal intussusception. In cases of mucosal prolapse, only the inner mucosal layer protrudes through the anus, leaving the muscular layers behind. In rectoanal intussusception the prolapsed tissue may be partial or full thickness, but remains confined to the rectal lumen. The type of prolapse will help direct the appropriate therapeutic option.

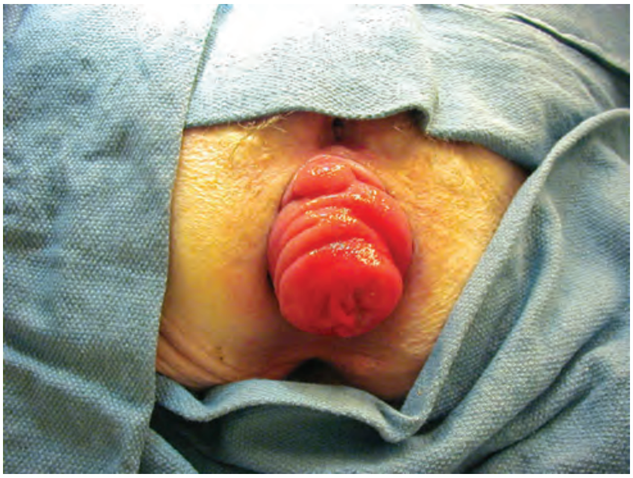

Figure 30.26 Full-thickness rectal prolapse. Note the concentric folds and palpable double wall of rectum.

The true incidence of rectal prolapse is unclear, although it is more common towards the seventh decade of life. The majority of these patients are elderly females. Patients with rectal prolapse often complain of a mass protruding from the anus, initially with straining then progressing to exteriorization with any increase in abdominal pressure and finally even at rest or simple movements. Chronic prolapse can result in an inflamed and ulcerated mucosa and bleeding. Faecal incontinence is a significant feature of full - thickness prolapse, which may be a consequence of sphincteric disruption or pudendal stretching.

The clinical assessment of rectal prolapse often requires reproduction of the prolapse. The patient may need to sit on a toilet and strain or use enemas to reproduce the event in order to fully evaluate the extent of prolapse. Full-thickness prolapse presents with concentric folds and double rectal walls on palpation, while mucosal prolapse is visualized as radial folds that do not protrude more than 3–5 cm.

Surgical management of rectal prolapse

Rectal prolapse surgery can be performed on patients in whom conservative measures have failed, and prolapse is causing significant reduction in quality of life. Surgery can be performed via the perineal route, which is less metabolically challenging, and suitable for patients who are more frail, or the abdominal route, which may be laparoscopic or open, and suitable for patients who are more physically fit.

Transperineal operations include perineal rectosigmoidectomy (Altemeier's procedure), which is a full-thickness excision and reanastomosis of the rectosigmoid, and Delorme's procedure, which is a mucosal excision and subsequent muscular plication. Neither procedure involves fixation of the rectum to a bony prominence. Both procedures are not technically demanding, and can be repeated as necessary. However, perineal procedures generally carry a recurrence rate in the region of up to 16% for perineal rectosigmoidectomy and 40% for Delorme's procedure at 5 years. Perineal procedures carry the advantage of having lower morbidity than abdominal procedures, with the absence of an abdominal incision, less adhesion formation, no intra-abdominal anastomosis and a relatively short hospitalization.

Abdominal operations include anterior resection of rectum and dorsal and ventral mesh rectopexy, plus or minus anterior resection. The fixation of rectum to sacrum may provide better results in treating rectal prolapse, and presents the lowest recurrence rate when combined with sigmoid resection (2–10%). Dorsal rectopexy frequently results in chronic constipation because of the necessary mesorectal dissection and damage to the hypogastric plexi of nerves. Ventral rectopexy has recently become popular, as it is associated with a significantly lower incidence of constipation. There have been reports of patients with ventral rectopexies requiring a posterior STARR procedure to address the angular change in the resultant rectum. The longevity of the rectopexy procedure is significant, with fewer than 5% recurrences over 5 years. The management of recurrent rectal prolapse depends on the previous procedure. Abdominal approaches should be avoided if the patient has undergone previous perineal rectosigmoidectomy, especially if sigmoid resection is contemplated, because of the potential ischaemia and necrosis of the intervening segment between anastomoses. A repeat rectosigmoidectomy can be safely performed in this patient group.

Other pathologies associated with constipation

Constipation may be caused by any stricturing lesion and carcinoma of the colon is a particular concern. Other possible causes are strictures due to diverticular disease, ischaemia and ulcerative colitis or Crohn's disease. Painful anal lesions such as fissure, abscess or prolapsed haemorrhoids may also give rise to constipation by inhibiting the wish to defecate.

Aganglionosis and/or myenteric plexus lesions

Other than drugs, constipation may be caused by malfunction of the intrinsic nervous system of the large intestine and this in turn can be subdivided into Hirschsprung disease and idiopathic megacolon and megarectum. These are dealt with as separate issues in the following sections of this chapter.

Constipation due to extracolonic factors

Extracolonic factors that may give rise to constipation include:

- illness causing immobility (e.g. myocardial infarction)
- neurological disorders
  - multiple sclerosis
  - Parkinson disease
  - autonomic neuropathy (e.g. diabetes)
  - spinal cord injury
- endocrine disorders
  - hypothyroidism
- connective tissue disorders
  - systemic sclerosis.

The most common endocrine abnormality leading to constipation is hypothyroidism, and individuals with myxoedema may develop megacolon. Hypercalcaemia may also present with constipation. There are various neurological causes of constipation. Patients with diabetes mellitus may have severe constipation owing to an associated autonomic neuropathy. These patients demonstrate loss of colonic activity after a meal and this may be reversed by neostigmine indicating intact postganglionic neurones. It is therefore worth trying prokinetic drugs in these patients. Spinal cord injury can give rise to colonic problems which depend on the site and severity of the lesion. Spinal cord transection above L2 gives rise to decreased colonic compliance and the loss of conscious control of the external sphincter function. However, defecatory reflexes are intact. This leads to constipation, but reflex emptying of the rectum can be brought about using enemas or suppositories. Injuries of sacral nerves and the cauda equina give rise to lack of control and loss of tone of the external sphincter muscles and this may lead to both constipation and incontinence. Multiple sclerosis may lead to severe constipation via mechanisms similar to spinal cord transection. Finally, Parkinson disease can be associated with constipation because of dystonia of the pelvic floor.

Psychological factors are clearly important in a proportion of patients with constipation. It may be a presenting feature of clinical depression and in patients with anorexia nervosa constipation may be a significant feature. However, there are a proportion of patients who complain bitterly of constipation but in fact when objective testing is carried out, normal colonic transit is demonstrated with normal passage of stool. If an individual perceives themselves to be constipated and yet objective evidence indicates that their defecatory habits are within the normal range, the best approach is a careful explanation of what can be regarded as normal.

Solitary rectal ulcer

The term solitary rectal ulcer is strictly a misnomer, as the lesions may be multiple and ulceration may not necessarily be present. Although any age can be affected it is most common in young adults. The macroscopic appearance is of a red thickened area of rectal mucosa usually with a shallow ulcer in the centre. Classically it is positioned on the anterior wall of the rectum opposite the puborectalis sling 5–8 cm above the anal verge. Histologically the lamina propria is replaced by collagen and there is fibromuscular replacement of the mucosa. The aetiology is unclear but it is now believed that it is due to internal rectal prolapse or intussusception which causes trauma to the rectal wall.

Clinically, all patients have difficulty in defecation which involves going to the toilet several times a day but only actually defecating once or twice. Usually there is deep-seated perineal pain and blood and mucus are often passed. On digital examination there is usually an indurated area on the anterior aspect of the rectum. The diagnosis is made by endoscopy and biopsy. If a rigid sigmoidoscopy is being used, asking the patient to strain down during the procedure may reveal the intussusception. However, the only accurate way of demonstrating an intussusception is by using defecating proctography.

Treatment can be difficult and a conservative approach should be taken in the first instance. A high-fibre diet and the use of suppositories may prevent excessive straining and alleviate the symptoms. Biofeedback may also be useful if there is obstructed defecation. Topical steroids have been recommended but there is little evidence that these have any effect. In extreme cases surgery may be indicated. If there is complete rectal prolapse then abdominal rectopexy is indicated. However, for internal intussusception the results of this procedure are poor. Thus for patients with extreme symptoms who do not have a complete rectal prolapse, rectal excision with coloanal anastomosis or even abdominoperineal resection of rectum may be indicated.

Colonic pseudo-obstruction

Acute colonic pseudo-obstruction or Ogilvie syndrome is characterized by marked dilation of the colon in the absence of mechanical obstruction. It nearly always occurs in hospitalized patients and the vast majority have an associated condition such as infection, widespread malignancy, recent surgery or trauma particularly to the spine. The underlying aetiology is not clear but it is a form of colonic dysmotility, which is the final common pathway of a variety of physiological and biochemical disturbances. As it is often associated with pelvic pathology, damage to the autonomic innervation of the distal colon has been implicated.

Clinical features

The clinical features of acute colonic pseudo-obstruction closely mimic acute large bowel obstruction. The patient often has colicky abdominal pain and progressive distension of the abdomen is the rule. Constipation is common, although not absolute, as some patients will continue to pass a small amount of flatus or liquid stool. Nausea and vomiting are also common. On examination there is massive abdominal distension and if the caecum is distended to such an extent that its viability is compromised there will be right iliac fossa tenderness. Bowel sounds are variable and can be normal or obstructive in nature. Digital examination of the rectum usually reveals an empty rectum.

Diagnosis

The diagnosis is generally made on plain abdominal radiograph, which shows the typical appearance of a distal colonic obstruction often with the cut-off in the descending colon. Measurement of the diameter of the caecum on the radiograph is important as perforation is common once this exceeds 12 cm. Unlike mechanical large bowel obstruction, the colonic haustral and mucosal pattern may be maintained and this also distinguishes it from the toxic megacolon of inflammatory bowel disease (IBD). However, the distinction between pseudo-obstruction and mechanical large bowel obstruction can be extremely difficult to make on plain abdominal radiographs and thus any patient with suspected mechanical large bowel obstruction should have this confirmed either by sigmoidoscopy or by water-soluble contrast enema before proceeding to surgery.

Complications

The main complication of pseudo-obstruction is faecal peritonitis secondary to perforation of the caecum.

Treatment

In the first instance, management consists of intravenous fluids, nasogastric aspiration and decompression with a flatus tube inserted at rigid sigmoidoscopy. Concomitantly, it is important to correct any metabolic disturbances, treat infections and stop any medications that may have an effect on colonic motility, e.g. narcotic analgesics, anticholinergic agents and calcium channel antagonists. If this does not bring about a rapid improvement, colonoscopy with decompression of the colon should be carried out. This reduces the diameter of the caecum in about 70% of cases, but in about 40% repeated colonoscopy will be required. Recurrence of the pseudo-obstruction can be decreased by placing a drainage tube into the right side of the colon at the time of the first colonoscopy.

A randomized study has shown that 2.0 mg of neostigmine given intravenously over 3–5 minutes can resolve pseudo-obstruction in a substantial proportion of patients. When the neostigmine has been given the patient should lie supine for 60 minutes and continuous ECG monitoring should be used to detect a bradycardia. If this occurs 1.0 mg of intravenous atropine should be given.

Surgery for acute colonic pseudo-obstruction is indicated if all these conservative measures fail to bring about a reduction in the size of the caecum. In the absence of signs suggesting ischaemia or perforation of the bowel, the operation of choice is a tube caecostomy through a limited right iliac fossa incision to expose the caecum. A large Foley catheter can then be used to intubate the caecum and this should be retained for approximately 3 weeks. However, if there are signs of ischaemia or perforation, a midline laparotomy should be used. If the bowel appears to be viable then a tube caecostomy will be satisfactory. However, if there is extensive necrosis a right hemicolectomy should be performed. Under most circumstances, an immediate anastomosis should be deferred and an ileostomy and mucus fistula fashioned. It should be remembered that colonic pseudo-obstruction is associated with a significant mortality, largely owing to the underlying illnesses which are associated with this condition. In patients in whom conservative treatment is successful the mortality is about 15%, whereas in those undergoing surgical intervention it is in the region of 30%.

Irritable bowel syndrome

IBS is not a precise diagnosis but rather a group of functional bowel disorders. It can be defined as abdominal discomfort or pain associated with defecation or a change in bowel habit and with an element of disordered defecation. In the West, IBS probably occurs in 15–20% of individuals, with a higher prevalence in women. The course of IBS is highly variable, but essentially it is a chronic relapsing condition.

Clinical features

The clinical features of IBS vary in number and severity. They consist of an abnormal stool frequency (more than three times a day or less than three times a week), abnormal stool consistency (hard, loose or watery), abnormal passage of stool (urgency, straining or tenesmus), the passage of mucus and abdominal bloating or distension.

Diagnosis

Because of the imprecise nature of the symptom complex in IBS, many patients with this condition will require diagnostic tests to exclude organic disease. Normally this will take the form of barium enema and sigmoidoscopy or colonoscopy. Certainly, if a patient has irritable bowel-type symptoms associated with rectal bleeding, weight loss or other suspicious symptoms, they should be thoroughly investigated. The diagnosis, however, rests on clinical features and the diagnostic criteria agreed at the multinational consensus meeting on functional gastrointestinal disorders held in Rome in 1999 are as follows.

At least 12 weeks (not necessarily consecutive) in the preceding 12 months of abdominal discomfort or pain that is associated with at least two of the following other features:

- relieved by defecation
- onset associated with change in stool frequency
- onset associated with change in stool consistency.

Treatment

The mainstay of treatment is a confident diagnosis coupled with reassurance. Other treatment strategies depend on symptom control. If constipation is a significant feature then dietary fibre should be increased by using wheat, bran or bulking agents. If diarrhoea is predominant then loperamide or diphenoxylate may be useful. For abdominal pain, anticholinergic or antispasmodic agents such as mebeverine may be of value. There is also some evidence that low-dose antidepressants may help.

Proctalgia fugax

The term proctalgia fugax means ‘fleeting rectal pain’. It is characterized by episodes of severe anal or lower rectal pain which last for a variable length of time, ranging from a few seconds up to several minutes. Although it is a recurring condition, episodes may be separated by many days, weeks or months. The prevalence in a community is not clear but may be in the region of 20%. The pain can be extremely severe and cause considerable alarm and although there are no specific diagnostic features, sigmoidoscopy should be carried out in order to exclude organic disease and to reassure the patient. The cause of the pain is probably smooth muscle spasm but the underlying cause is obscure. Treatment is usually unnecessary as the attacks are of short duration and infrequent but in patients with frequent proctalgia fugax inhalation of salbutamol may curtail episodes of pain. Clonidine or amyl nitrate has also been recommended.

Colonic diverticular disease

The term ‘diverticular disease’ describes a broad range of clinical pathology relating to the presence of symptomatic colonic diverticula. The disease presents variably, ranging from mildly symptomatic fluctuation in bowel habit and left lower quadrant abdominal pain, through haemorrhage and localized sepsis to colonic fistulation, perforation and life-threatening peritonitis. In addition, symptoms may present as an isolated occurrence, or develop into a chronic complaint. Considered a disease of Western society and of elderly patients, its incidence is rising together with associated episodes of hospitalization. Despite the significant associated healthcare burden, the aetiology, natural history and optimal management of this disease remains controversial.

The terminology applied to describe the different clinical presentations and disease stages associated with diverticular disease can be variable. ‘Diverticulosis’ refers to the presence of asymptomatic diverticula within the colon in the absence of associated inflammation. The term ‘diverticulitis’, typically prefixed as ‘acute’ on symptomatic presentation, can represent a wide spectrum of inflammatory change from localized subclinical inflammation to generalized peritonitis. This term is used interchangeably with ‘diverticular disease’, although this more commonly describes patients running a more indolent course of disease. Both diverticulitis and diverticular disease can be further described as ‘uncomplicated’ or ‘complicated’. ‘Uncomplicated’ disease refers to presentations in keeping with localized colonic inflammation, including left-sided abdominal pain, fever and leucocytosis. ‘Complicated’ diverticular disease describes disease which has progressed beyond local inflammation to one of the known sequelae of abscess formation, colonic stricture, obstruction, haemorrhage, fistula or perforation. The term *mychosis* is used in the context of diverticular disease to describe muscular shortening and thickening of the colonic wall, commonly seen at surgery.

The first noted reference to colonic diverticula as a pathological entity was made by the French surgeon Alexis Littre in the 1700s, although this was not in relation to diverticular disease *per se*. The current terminology stems from Fleischman, who used the term ‘divertikel’ in 1815. The pathology we recognize today as diverticular disease was first described by Jean Cruvehiler in 1849. Its absence from early surgical textbooks at this time suggests the disease was not as prevalent, or not as recognized, as today. Mayo reported the first surgical resection for complicated diverticulitis in 1907, advocating primary resection, although the disease remained uncommon. Although this case series promoted primary resection, staged resection consisting of drainage and stoma, interval resection and subsequent stoma reversal remained routine until the development of alternative treatment paradigms in the modern era.

Similarly, elective surgery for recurrent disease has seen a step-change in recent years. Parks’ landmark study in 1969 suggested that recurrent disease was more virulent, and more likely to require surgery, hence elective resection was frequently recommended. The original findings of this study have been challenged in recent years, and current research suggests a more benign course of recurrent disease. This, along with the not insignificant morbidity associated with elective resection, means that several of the commonly accepted treatment algorithms for diverticular disease are currently in the process of being redefined.

Diverticular anatomy

Macroscopically, colonic diverticula are acquired saccular protrusions of the colonic wall consisting of colonic mucosa. They do not contain all layers of the bowel wall, are therefore not regarded as true diverticula, and are instead termed *false, pulsion* or *pseudo* diverticula. Typically small in size, ranging from 0.5 to 1.0 cm, they occur at points of weakness where the vasa recta blood vessels penetrate the bowel wall (Figure 30.27). They most commonly protrude in four rows situated between the antimesenteric and mesenteric taenia. Colonic diverticula most frequently occur in the sigmoid and left colon and in patients with diverticulosis 90% will have sigmoid involvement. Of note, proximal right-sided colonic diverticula most frequently seen in Asian populations are true diverticula, involving all layers of the bowel wall and therefore may be unrelated phenomena.

Epidemiology and natural history

Although rarely seen in developing regions, the disease is common in the Western world and its incidence increases with age. Establishing the prevalence of diverticulosis is difficult, given that it is by definition asymptomatic. Previous estimates suggest that 40% of 60-year-olds will have developed diverticula, progressing to more than 80% of 85-year-olds.

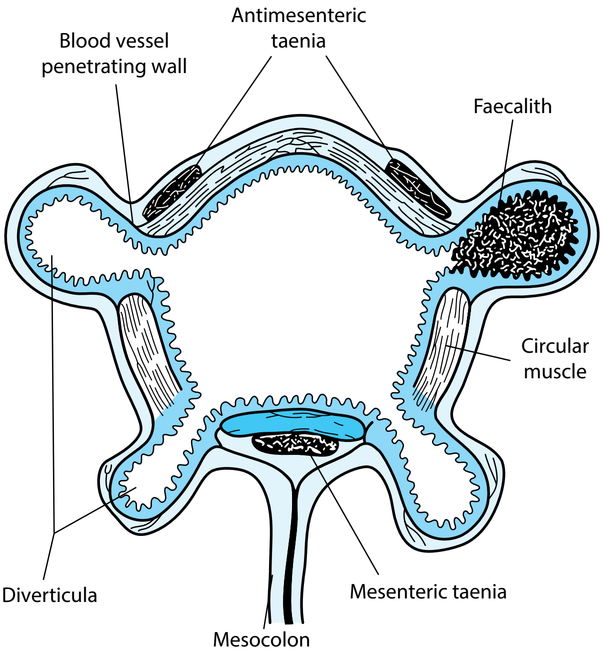

Figure 30.27 Structural abnormalities in diverticular disease.

Most patients with diverticulosis will not experience any complications related to this; however, a proportion with colonic diverticula will go on to develop symptomatic diverticular disease. The proportion affected is difficult to establish given the uncertainties surrounding the true prevalence of diverticulosis; however, it is estimated to be in the range of 10–25% with an average age of 62 years at presentation. Diverticulitis is uncommon in the young, with only 2–6% of patients affected under the age of 40 in one study. Approximately 5–15% of patients will develop bleeding complications from diverticulosis in the absence of diverticulitis (Figure 30.28). Early epidemiological studies suggested an increased male incidence; however, more recent studies now indicate a female predominance. The increased range of potential diagnoses for left - sided lower abdominal pain in women and the relatively greater proportions of elderly women than men may confound this.

Data relating to hospital admissions suggest an absolute prevalence of diverticular disease of 60/100 000 admissions in the USA. Although the disease was infrequently encountered before the twentieth century, numerous studies suggest that the incidence of symptomatic disease continues to increase in industrialized populations. In England, the NHS national admission rate increased from 0.56 in 1996 to 1.20 per 1000 population/year in 2006, with 54% aged over 70 years. In this study surgery was undertaken in 16.3% of admissions from 1996 to 2006, with 58% of cases performed on an emergency basis. The age-adjusted adult incidence of perforation has been estimated as 35 per 100 000 per annum in the UK.

Risk of recurrence has been the subject of much recent controversy, given that previously reported rates determined the policy for offering elective colonic resection early as a preventative measure. Parks' original paper in 1969 reported a readmission rate of 25% with diverticulitis. In addition, with each admission the patient was less likely to respond to medical management with increasing associated mortality. The findings of this study are now in doubt. A more recent large-scale US study

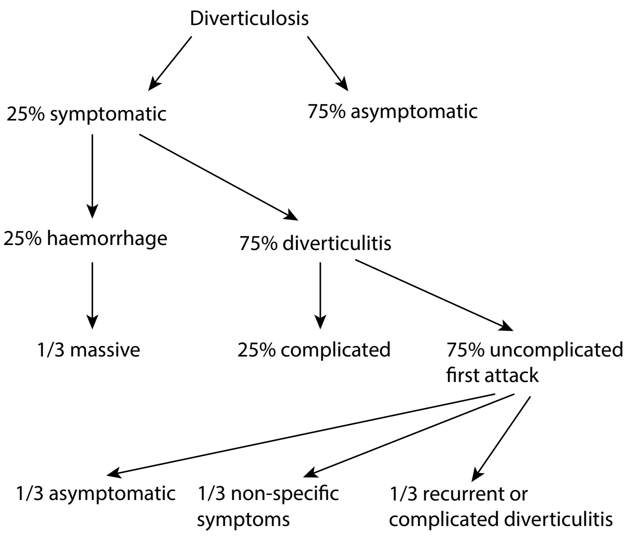

Figure 30.28 Natural history of diverticular disease. (Adapted from Fearnhead NS, Mortensen NJ, *Best Pract Res Clin Gastroenterol* 2002;**16**:577–593.)

by Broderick-Villa and colleagues suggests that the recurrence rate after hospitalization with an initial episode of diverticulitis treated medically is about 1.5% per year. Another modern large series indicated that only 3% of patients required emergency operations during 10 years of follow-up. Subsequent attacks of diverticulitis therefore appear to be similar to previous ones. Such data have led to the adoption of a more conservative treatment strategy in many centres for those hospitalized with diverticulitis.

Recent research into the role of acute diverticulitis in the development of complicated colonic diverticular disease by Humes and colleagues has suggested that most patients with complicated disease do not experience episodes of acute diverticulitis beforehand. This analysis of the UK General Practice Research Database linked to national Hospital Episode Statistics also revealed a significant excess mortality associated with complicated disease ranging from a 4.5-fold increase in those suffering from perforation or abscess to a 2.5-fold increase in those with a fistula or stricture. In this study, increasing episodes of diverticulitis were associated with an increased risk of developing a fistula (odds ratio 1.54), but there was no clear association with perforation or abscess.

Free perforation, while previously thought to be a potential complication of recurrent complicated disease, is now known to occur most frequently at a first attack of diverticulitis. In a UK study, Morris and colleagues used regional hospital coding databases and local population data to estimate the age-adjusted incidence of perforation as approximately 3.5 per 100 000 per annum. The mortality in those undergoing surgery was 23%, which compares to other studies reporting mortality ranging from 4% to 36%.

Aetiology and pathogenesis

The aetiology and pathogenesis of diverticulosis have not been conclusively proven and are potentially multifactorial. Theories relate to structural abnormalities of the colonic wall, motility or neuromuscular abnormality, and the role of dietary fibre. The most commonly cited hypothesis relates to the wide discrepancies in geographical incidence of the disease. Painter and Burkitt suggested in 1971 that the frequency with which the disease was seen in industrialized countries compared with developing nations related to the diet changes that took place in industrialized countries during the 1800s. Decreased dietary fibre, particularly through the consumption of processed food and roller milling of floor, was shown to reduce stool transit time and reduce stool weight. From this, it was proposed that resulting exaggerated colonic circular muscle contractions caused colonic wall hypertrophy as seen in sigmoid diverticular specimens. These contractions segmented the colon, increasing intraluminal pressure as confirmed on manometry studies (and as predicted by Laplace's law). This in turn could lead to the mucosal herniation through weak points in the bowel wall, as seen in diverticulosis.

Subsequent research has not demonstrated hypertrophy or hyperplasia of the taenia coli smooth muscle cells themselves, and it has been proposed that the thickening seen is caused by elastin deposition in a contracted form, leading to bunching of the taenia. Collagen abnormalities have also been implicated, with increased levels of cross-linkage in colons affected by diverticular disease. This would reduce colonic wall compliance, with resulting injury to the submucosa potentially allowing mucosal herniation to occur. Reports of diverticular disease in young patients with Ehlers–Danlos and Marfan syndrome have been cited in support of this. These structural abnormality theories remain an area of research.

Other theories relate to abnormalities of the neuromuscular apparatus in the bowel wall. Bassotti and colleagues have demonstrated that interstitial cells of Cajal and glial cells are decreased in colonic diverticular disease, potentially contributing to the disturbances in motility. Studies have investigated changes in serotonin signalling, given its importance in gastrointestinal motility. One indicated an increased presence of serotonin cells in the colonic mucosa of patients with diverticular disease. Others found attenuation of 5-HT transporter expression and function following recent acute diverticulitis.

Several studies lend support to the traditional dietary fibre hypothesis, showing a correlation between fibre intake and diverticular disease. The American Health Professionals Follow-Up Study showed an inverse correlation between dietary fibre and symptomatic diverticular disease with a relative risk of 0.58. The recent European Prospective Investigation into Cancer and Nutrition (EPIC) concluded that eating a vegetarian diet and a high intake of dietary fibre was associated with a lower risk of admission to hospital or death from diverticular disease. Vegetarians had a 31% lower risk of diverticular disease than meat eaters, confirming a risk seen with meat eaters in other studies. Despite this, there is little evidence behind the common recommendation of increasing dietary fibre intake to prevent diverticulitis; this has been extrapolated from the established correlations.

Most importantly, these hypotheses do not explain the pathogenic mechanism between the development of diverticulosis and subsequent diverticulitis. Similarities with both appendicitis and IBD have been drawn. Stasis or obstruction may lead to bacterial overgrowth and the resulting diverticula and colonic inflammation. Initial theories for this related to diverticular obstruction by a faecalith or food particle, leading to local inflammation and potential perforation. At a histological level, similarities are seen with the appearances of IBD, and several studies are currently exploring the role of aminosalicylate compounds in the treatment of diverticular disease. It has been suggested that some overlap between the diseases may exist. Additional theories include changes in colonic microbiota, ischaemia and visceral hypersensitivity which may all contribute to symptomatology.

Risk factors for diverticular disease

In addition to the risks conveyed by age, dietary fibre intake and geographical distribution of diverticular disease already highlighted, there are a number of other associated risk factors highlighted in epidemiological studies. Evidence is currently lacking as to whether these proven associations are causative and whether changing these risks will subsequently change the risk of developing diverticulitis or further attacks.

Body mass index

Body mass index (BMI) is highlighted as a risk factor in a number of studies, with an association between higher BMI and diverticulitis. Strate and colleagues showed most recently in a prospective cohort study of 47 228 male health professionals that men with a BMI ≥30 kg/m^2 had a relative risk of 1.78 for diverticulitis. A higher risk of diverticular bleeding was also noted. Rosemar and colleagues showed a linear increase in risk of diverticular disease with increasing BMI in men in a large Swedish cohort study with 28 years of follow-up, with a maximum hazard ratio of 4.4 for a BMI of ≥30.

Physical activity

Physical activity is associated with decreased rates of diverticular disease. Aldoori and colleagues showed that after adjustment for age, energy-adjusted dietary fibre and energy-adjusted total fat, overall physical activity was inversely associated with the risk of symptomatic diverticular disease with a relative risk of 0.63. The National Runners Health study revealed decreased incidence of diverticular disease of 6.2% per km/day after adjusting for age, sex and reported dietary intake.

Medication

Large cohort studies have linked a number of prescription medications with diverticular disease and its complications with non-steroidal anti-inflammatory drugs (NSAIDs). An analysis of the Health Professional Follow-up Study showed that after adjusting for risk factors aspirin use was associated with an increased risk of diverticulitis and diverticular bleeding. Users of non-aspirin NSAIDs were also at increased risk. In a case–control analysis of the UK General Practice Research Database, Humes and colleagues demonstrated a two- and threefold increase in the risk of diverticular perforation with opiate analgesics and oral corticosteroids respectively.

Smoking

Smoking has a potential association, although studies to date have provided contradictory results. Rosemar identified it as an independent risk factor (hazard ratio 1.6) in the male Swedish cohort study. In another Swedish study, the Swedish Mammography cohort, female smokers or past smokers had a higher risk of symptomatic diverticular disease (relative risk 1.89 and 1.26 respectively). However, Aldoori and colleagues did not see this association in the US Health Professionals Follow-up Study.

Classification of diverticular disease

Comparison between patients and clinical outcomes in diverticular disease is hindered by the differing presentations of uncomplicated vs complicated disease, and the varied way in which complicated disease manifests. Several classifications or scoring systems for the severity of disease have been published. The adoption of different classification systems in different publications has not always helped clarify this area.

Table 30.2 Hinchey classification and modified Hinchey classification by Sher *et al.*

Hinchey classificatio	Modified Hinchy classification (Sher *et al.*)
I Pericolic abscess of phlegmon	I Pericolic abscess
II Pelvic, intra-abdominal or retroperitoneal abscess	IIa Distant abscess amenable to percutaneous drainage IIb Complex abscess associated with fistula
III Generalized purulent peritonitis	III Generalized purulent peritonitis
IV Generalized faecal peritonitis	IV Faecal peritonitis

Table 30.3 Clinical classification of diverticulitis (adapted from Kohler *et al.*)

Grade	Clinical description	Symptoms
I	Symptomatic uncomplicated disease	Fever, crampy abdominal pain, CT evidence of diverticulitis
II	Recurrent symptomatic disease	Recurrence of above
III	Complicated disease	Haemorrhage Abscess Phlegmon Perforation Purulent and faecal peritonitis Stricture Fistula Obstruction

Most widely used internationally is the Hinchey classification, proposed in 1978 and later modified by Sher and colleagues in 1997 (Table 30.2). This is used to classify the severity of clinical insult resulting from perforated diverticular disease. Originally based on operative findings, the availability of CT imaging has extended its utility and allowed appropriate categorization of related abscess as recognized in Sher's modification. Further modification has subsequently been proposed by Wasvery and colleagues, adding a stage 0 for uncomplicated disease and introducing Ia and Ib to represent pericolic inflammation or phlegmon and pericolic abscess, respectively.

The Hinchey classification does not take into account existing conditions that may have an impact on clinical course or outcome; however, it allows an approximation at outcome based on the findings of previous studies, with risk of death <5% for stage 1 or 2 disease, ~13% for stage 3 and ~43% for stage 4 disease.

Köhler and colleagues through the European Association for Endoscopic Surgeons proposed a classification based on clinical severity and presentation, dividing this into symptomatic uncomplicated, recurrent symptomatic and complicated disease by complication. Given the subjective nature of clinical presentation for symptomatic uncomplicated and recurrent symptomatic disease, this is limited in its applicability due to the risk of incorporating an incorrect clinical diagnosis (Table 30.3).

In the European literature the Hansen–Stock classification has been widely used. This classifies the disease clinically by stage depending on its severity.

Siewert and colleagues suggested a similar classification solely for acute complicated diverticulitis based on anatomical location of an abscess (Table 30.4).

Table 30.4 Hansen–Stock and Siewert classifications of diverticular disease and diverticulitis

Hansen–Stock classification	Siewert classification
0 Diverticulosis I Acute uncomplicated diverticulitis II Acute complicated diverticulitis	
IIa Phlegmon, peridiverticulitis	I Pericolic abscess or phlegmon
IIb Abscess, sealed perforation	II Pelvic, intra-abdominal or retroperitoneal abscess
IIc Free perforation	III Free perforation
III Chronic recurrent diverticulitis	

Table 30.5 Ambrosetti's CT staging of diverticulitis (Adapted from Ambrosetti *et al.*)

Moderate diverticulitis	Severe diverticulitis
Localized sigmoid wall thickening (<5 mm)	Abscess
Inflammation of pericolic fat	Extraluminal air
	Extraluminal contrast

Ambrosetti and colleagues have described a classification system describing diverticulitis as moderate or severe according to CT criteria. Although limiting its application to patients who have therefore undergone CT imaging, it is useful in assisting decision-making by allowing patients to be categorized into optimal pathways for management (Table 30.5).

The most recent addition to this classification structure has been suggested by Klarenbeek and colleagues in 2011. This represents an attempt to combine the existing classifications into one clinically applicable system, including the most recent developments in imaging modalities and treatments (Table 30.6).

Other scoring systems may also be utilized in the setting of classifying diverticular disease such as the Peritonitis Severity Score, the Mannheim Peritonitis Score or Colorectal-POSSUM (Physiological and Operative Severity Score for the enUmeration of Mortality and Morbidity). These are not specific to diverticular disease, but are useful in the estimation of patient risk and unit outcome audits.

Clinical presentation

The majority of patients with diverticulosis remain asymptomatic. Symptomatic diverticular disease presents with a broad range of clinical manifestations, resulting from the variable nature of the disease. Symptoms may mimic those of a number of other conditions. This can take the form of acute uncomplicated,

Table 30.6 Klarenbeek classification of diverticular disease

Classification	Clinical presentation	Imaging	Treatment
A	Uncomplicated disease • Pain in left lower quadrant • Fever • Changes in relief pattern	CT scan or ultrasound • Phlegmon • Small abscess in bowel wall Colonoscopy • Diverticulosis • Inflammation	Conservative treatment • Antibiotics[a] • Low - residue diet[a] Prevention • Fibres • Prevention of obesity • Treatment of comorbidity • Mesalazine[a]
B	Chronic complicated disease • Impaired passage of stool • Presence of fistula • Recurrent rectal blood loss • Incapacitating complaints • High-risk patients	CT scan • Stenosis • Fistula Colonoscopy • Stenosis • Fistula • Blood in diverticula	Elective intervention Sigmoid resection with primary anastomosis • Open • Laparoscopically
C 1	Acute complicated disease • Fever • Painful mass	CT scan • Large abscesses (>5 cm)	Acute intervention Percutaneous drainage
2	• Ileus	CT scan • Intenstinal obstruction	Sigmoid resection with primary anastomosis Hartmann's procedure
3	• Massive rectal blood loss	CT angiography • Contrast blush colonoscopy • Active diverticular bleeding	Sigmoid resection with primary anastomosis • Open • Laparoscopically Endoscopic intervention[a] Endovascular coiling[a]
4	• Generalized peritonitis	CT scan • Pneumoperitoneum • Extraluminal contrast • Free fluid	Diagnostic laparotomy/laparoscopy • Resection with primary anastomosis • Hartmann's procedure • Lavage and drainage[a]

[a] Experimental or non - evidence - based treatement.

chronic uncomplicated or complicated disease. Thus the spectrum of differential diagnosis in diverticular disease is wide:

- urological
  - cystitis
  - pyelonephritis
  - neoplasia
- gynaecological
  - pelvic inflammatory disease
  - ectopic pregnancy
  - ruptured ovarian cyst
  - ovarian torsion
- gastrointestinal
  - colorectal neoplasm
  - ischaemic/infectious colitis
  - IBD
  - irritable bowel disease
  - appendicitis (with right-sided sigmoid colon)
- other
  - ruptured iliac artery aneurysm
  - rectus sheath haematoma.

Chronic uncomplicated diverticular disease

Chronic uncomplicated diverticular disease may present as episodic abdominal pain localized to the left lower quadrant, altered bowel habit and abdominal distension. The potential differential diagnosis is large, and the overlap with symptoms of irritable bowel disease can be significant making outpatient diagnosis difficult without further investigation. It is often diagnose when other more 'serious' pathology has been excluded. In the elderly patient group a new diagnosis of diverticular disease is frequently reached when the symptoms trigger investigation to exclude an underlying carcinoma.

Acute uncomplicated diverticular disease

Acute uncomplicated diverticular disease classically presents as abdominal pain localized to the left lower quadrant, often associated with a mild fever and leucocytosis. The picture may be variable, and right - sided abdominal pain is not infrequently seen particularly in patients with a long loop of redundant sigmoid colon lying to the right of the midline. Gastrointestinal disturbance is common, with anorexia, nausea and vomiting, constipation and/or diarrhoea frequently reported. Urinary symptoms may also occur secondary to proximity of the bladder to an inflamed sigmoid colon.

Complicated diverticular disease

Complicated disease presents according to the nature of the complication, which is predominantly abscess formation, perforation, fistulation, haemorrhage, stricture or obstruction.

Abscess formation is the most common sequela of acute complicated diverticulitis, occurring in approximately 15% of patients. Classic symptoms are in keeping with abscesses elsewhere in the body, namely spiking fever and lassitude potentially accompanied by rigors. Typical locations are pelvic and pericolic, although retroperitoneal sepsis may also develop. The severity of the infection is most commonly classified using the Hinchey classification following CT. A significant localized abscess may progress into a free perforation.

Perforation secondary to diverticular disease occurs in 1–2% of patients and is a potentially life-threatening complication associated with high morbidity and mortality. The term can describe either perforation of a diverticular abscess leading to purulent peritonitis or faeculent peritonitis from contamination of the peritoneal cavity with stool. Most commonly occurring with a first attack of diverticular disease, patients may not present with a history of diverticulitis. Presentation is similar to a generalized acute abdomen from other causes. The severity of the accompanying septic shock arising from purulent or faeculent peritonitis may help distinguish it from an upper gastrointestinal perforation and chemical peritonitis seen with, for example, a duodenal perforation.

Fistulation occurs in approximately 2% of patients with diverticular disease, and are included in the indications for surgery in 17–27% of patients. They arise from an inflamed colon and associated abscess decompressing into adjacent organs. Most often, this leads to a colovesical, colovaginal fistula, although colouterine, coloenteric and colocutaneous fistulas can occur. Often these patients do not report other associated symptoms and will initially be referred to a urologist or gynaecologist for further investigation. Symptoms are variable depending on the structures involved, although the patient is not usually acutely unwell, as any contained abscess has discharged in order to create the fistula. Colovesical fistulas account for approximately 65% of diverticular disease-related fistulas, and are suggested by recurrent urinary tract infections associated with enteric organisms, pneumaturia or faecaluria. Colovaginal fistulas account for 25% of cases and present with the passage or flatus of faecal material per vagina. Both colovesical and colovaginal fistulas are more common in women who have previously undergone hysterectomy, and it has been hypothesized that the uterus may act as a buffer, preventing the inflamed sigmoid colon reaching the bladder or vagina. Altman and colleagues reported that, compared with women who had neither hysterectomy nor diverticulitis, the risk of fistula surgery increased fourfold in hysterectomized women without diverticulitis, sevenfold in non-hysterectomized women with diverticulitis and 25-fold in hysterectomized women with diverticulitis. In all cases of fistulation, the possibility of an underlying malignancy or IBD giving rise to this should also be excluded.

Haemorrhage is not usually associated with acute diverticulitis, but usually in isolation and/or as a result of underlying diverticulosis. It most likely arises from rupture of a blood vessel involved in the herniated mucosa of a diverticulum. As the most common cause of acute lower gastrointestinal bleeding, accounting for up to 40% of cases, it is typically painless, with the only heralding symptom being the urge to defecate. Clots may be passed and the colour of the blood will be variable depending on how proximal the source is located within the colon. Unlike upper gastrointestinal bleeding, although it may initially be profuse, diverticular bleeding is typically self-limiting and resolves without need for significant intervention.

Approximately 30% of cases are associated with severe blood loss and cardiovascular compromise, although surgical intervention will be required in only 10% of these. In elderly patients, the increasing prevalence of NSAIDs and anticoagulation therapy can complicate management.

Stricture or obstruction at first presentation can be difficult to distinguish from colonic adenocarcinoma, even following radiological imaging, and the diagnosis may not be made until the lesion is resected and histologically examined (Figure 30.29). Stricturing is more common than obstruction, and is thought to develop through repeated episodes of inflammation leading to fibrosis. Patients complain of narrowed stools and constipation, varying according to the degree of structure. Approximately 10% of large bowel obstructions arise secondary to diverticular disease, and small bowel obstruction may also develop through adherence of a loop to an inflamed segment of colon or inflammatory mass. When associated with an episode of acute diverticulitis the obstruction may be functional secondary to colonic oedema and localized sepsis, and will resolve with medical treatment.

Atypical presentations may be seen in the most elderly patients or immunocompromised patients unable to mount a typical systemic inflammatory response. Abdominal pain may not reflect the severity of the clinical problem and overt signs of sepsis may be absent. Evidence suggests higher rates of abscess and free perforation in immunocompromised patients, and they are additionally more likely to fail medical management. These patients should be managed expectantly with close observation, early imaging, and a low threshold for intervention.

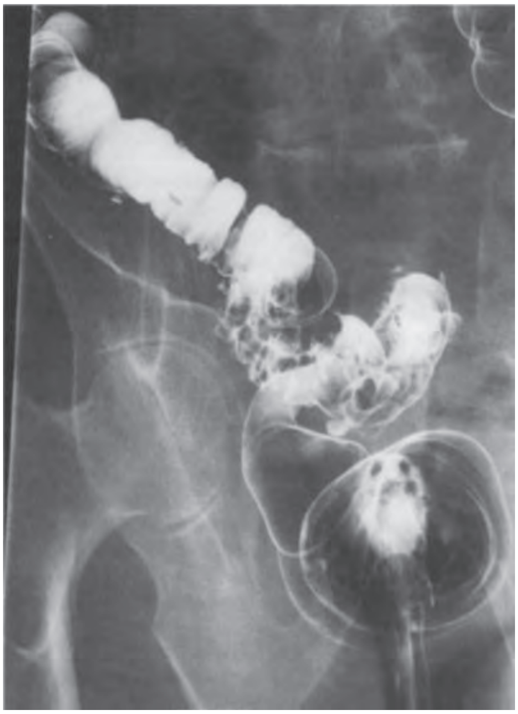

Figure 30.29 Barium enema showing a typical sigmoid diverticular stricture. Note that although the narrowing is marked, the mucosal pattern within the stricture is preserved.

Investigation

Colonoscopy

Colonoscopy is controversial in the acute setting because of the potential risk of an iatrogenic perforation of the inflamed colonic wall, or converting a sealed microperforation into a free perforation. It does however play an important role in investigating the cause of acute symptoms in the aftermath of such an attack, and is typically performed 6–8 weeks later when the inflammation has subsided. Westwood and colleagues have recently questioned this tradition of endoscopic follow-up, given the advent of routine CT on an inpatient for the majority of patients presenting as an acute hospital admission. In their study of 205 patients with acute uncomplicated diverticulitis undergoing colonoscopic investigation following diagnostic CT they showed a yield of 5.4% for advanced colonic neoplasia and 0.5% for colorectal cancer. This equated to the yield for screening asymptomatic individuals and they suggested that in this group of patients CT alone may be considered sufficiently sensitive to exclude the need for further interval endoscopic investigation in all patients. The other common indication for endoscopy is in the investigation of lower gastrointestinal bleeding. In the acute setting this may be hindered by the presence of blood within the lumen compromising the view. Endoscopy is also mandated in the investigation of stricture, when biopsies may be helpful in diagnosing the aetiology, and in the investigation of suspected diverticular fistula (Figure 30.30).

Ultrasound

Ultrasonography is frequently used in place of CT in European centres. With a reported sensitivity of 84–98% and a specificity of 80–97% in studies, it useful non-invasive, non-ionizing investigation on which acutely inflamed diverticula can be demonstrated. Abdominal ultrasound also has an important role in identifying other potential causes of acute symptoms, particularly relating to gynaecological causes in female patients. It can also be utilized to monitor a known abscess or mass. Uptake of ultrasonography for diagnosis of diverticular disease has not been universal however due to the operator-dependent variability and localized imaging window provided, which may

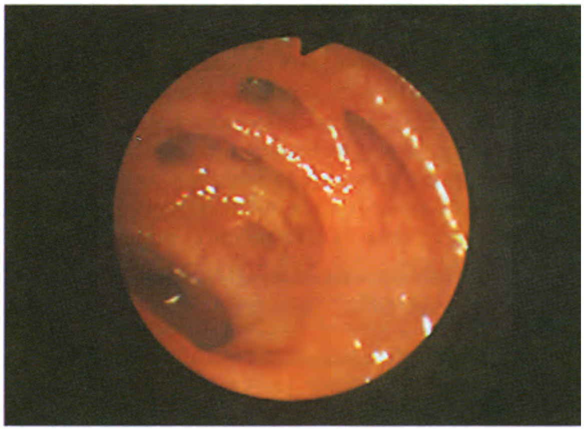

Figure 30.30 Colonoscopic appearances of diverticular disease. Note that in severe disease such as this it can be difficult to distinguish between the lumen and the mouths of the diverticula.

miss other important related findings elsewhere in the abdomen or pelvis.

Computed tomography

CT is considered the primary diagnostic investigation in the acute setting by many, and diagnoses acute diverticulitis with a sensitivity approaching 100% and a specificity of 95%. The main benefit surrounds its ability to identify alternative pathology in the acute setting. In addition, it provides the best modality for characterizing extramural disease and abscess, which have led to a number of diverticular disease classifications based on CT findings as discussed earlier in this chapter. This categorizing of patients can be useful in guiding subsequent clinical management. The most frequent findings consistent with acute diverticular disease are bowel wall thickening, fat stranding and diverticula. Rectal contrast may also be used to help delineate suspected fistula tracts, or demonstrate perforation. CT is also a useful therapeutic tool for percutaneous drainage of intra-abdominal abscesses. The main concerns relate to exposure to ionizing radiation, particularly in younger patients.

Contrast studies

Contrast studies were historically used routinely prior to the advent of widespread access to CT for initial investigation of suspected diverticular disease. Water-soluble single-contrast enema has now largely been superseded by CT, although it remains an option in resource-poor environments. It may help identify intramural changes and leakage of contrast may aid diagnosis of perforation or fistula; however, it does not provide information relating to extramural disease.

Further investigations

Other investigations may also be required in complicated disease, depending on the specific presentation and concerns. In significant lower gastrointestinal bleeding, mesenteric angiography may be used in order to localize the bleeding point within the colon. This may then be treated radiologically or guide surgical resection. In suspected diverticular fistulation, cystoscopy may be useful in identifying vesical openings and ruling out other urological disease causing symptoms.

Treatment

The optimal treatment of diverticular disease is an area in evolution and the subject of active research. Traditional management recommendations are being questioned, with an increasing move towards conservatism. New medical therapies are being investigated, and new paradigms in surgical management are being proposed.

Medical treatment

For mild, uncomplicated diverticulitis outpatient management with or without antibiotics may be appropriate, depending on the patient's individual situation. Further investigation may be undertaken if warranted after the episode has resolved. If outpatient management fails then hospitalization is required for more active treatment. For patients presenting with more acute systemic symptoms including fever, pain and inability to tolerate oral intake then hospitalization is appropriate from the outset. Supportive therapy, including antimicrobial therapy, gut rest, intravenous fluids and analgesia may be required together with radiological imaging to confirm diagnosis and stratify treatment. A proportion of patients will fail medical therapy, and approximately 15% of patients develop pericolonic or intramesenteric abscess. In these cases radiological or surgical intervention may ultimately be required.

Antibiotics remain the main therapy for symptomatic diverticular disease. The precise regimen will depend on local recommendations; however, typically these will be chosen to cover both aerobes and Gram-negative micro-organisms. In cases of severe sepsis these may be given parenterally until the sepsis is controlled, followed by oral administration. Guidance on the optimum duration of oral antibiotic therapy is lacking, but this will typically be prescribed for 7–10 days.

Currently the role of antibiotics in mild uncomplicated diverticular disease is being questioned. In Europe there is a trend towards avoiding antibiotic therapy in these cases, whereas in North America antibiotics are more frequently administered. A Scandinavian study has suggested bowel rest alone in these cases is similar in efficacy to antibiotic therapy. This area is currently being examined further in the DIABOLO trial, a large multicentre randomized control trial in Europe which is investigating a liberal policy, without antibiotics and without the strict requirement for hospital admission. The clinical and economic results are awaited.

Risk factor modification is a traditional component of medical therapy based on demonstrated associations, although the evidence that modifying these risk factors imparts a beneficial effect is largely lacking. Increasing dietary fibre, weight loss, smoking cessation and regular physical activity may play a role in reducing the frequency or severity of the disease.

Emerging medical therapies include the use of aminosalicylates and probiotics, and active studies continue to investigate their role. Low-grade proinflammatory states are associated with active diverticular disease; therefore, immunomodulatory agents such as 5-aminosalicylic acid (5-ASA) compounds used in the treatment of IBD have garnered interest as potential agents for treating diverticular disease or preventing symptomatic attacks. A meta-analysis of several small trials investigating 5-ASA products in the treatment of diverticulitis has confirmed improved outcomes; however, the results must be interpreted cautiously until larger objective trials have been conducted. Probiotics have been investigated as a similar potential treatment for altering the inflammatory milieu seen in diverticular disease. It has been theorized that the altered bowel motility and transit time may change the colonic microflora. Probiotics are live micro-organisms, the ingestion of which may restore normal colonic microflora. The beneficial effect of this treatment is yet to be clearly demonstrated.

Radiological intervention

If systemic symptoms and signs of sepsis continue despite optimum antimicrobial therapy, the presence of a diverticular abscess should be suspected. Following confirmatory CT imaging, percutaneous radiologically guided abscess drainage may bring the sepsis under sufficient control for antimicrobial therapy to succeed without further surgical intervention. Despite this, radiological drainage may fail and approximately 20–30% of cases will ultimately require surgical drainage.

The options for radiological intervention depend on the size, nature and anatomical location of the abscess(es). A single, small, well-contained abscess <5 cm in size may ultimately respond to antimicrobial therapy alone. Percutaneous drainage tends to be reserved for an abscess ≥5 cm in size. Multiple or multiloculated abscesses may still be drained; however, the failure rate is higher. Pelvic collections may be difficult to drain percutaneously, although transrectal, transgluteal or transvaginal drainage is an option. Typically a drain will be left in the collection until drainage is minimal, and samples of the fluid drained should be sent for appropriate microbiological investigations to ensure optimum antimicrobial therapy. Radiological intervention is also appropriate for patients with lower gastrointestinal bleeding secondary to diverticulosis. Most cases spontaneously settle with conservative management, although acute ongoing or recurrent massive bleeding may require further intervention.

In cases posing a continuing problem investigation can be undertaken with tagged red cell nuclear scans. More sensitive than mesenteric angiography, these can detect bleeding rates as low as 0.1–0.5 mL/min, although at a lower resolution. Nonetheless, undetectable bleeding obviates the need for invasive mesenteric angiography. Radionuclide suffers from a high rate of false localization due to tagged red cell migration in the bowel and overlying bowel loops. This ranges from 14% to 25% in reported studies, hence directed segmental resection for bleeding should not be performed on this basis alone.

In acute cases, and where the facilities and appropriately trained radiologists are available, the first - line treatment is mesenteric angiography to identify the bleeding point, with selective embolization of the feeding vessel to control this. One large Australian series reported a success rate of 76% associated with embolization, but in order to do this active bleeding must be present to allow the bleeding point to be located. Bleeding rates of 1–3 mL/min are the minimum that can be identified radiologically. In this series it was seen in only 48% of patients, and amenable to embolization in 45%, although lack of active bleeding is clinically reassuring. This procedure is not without risk, and cases of ischaemic bowel, false aneurysm and sepsis are reported, along with the risk of further major bleeding.

Surgical treatment

Surgical intervention is reserved for cases in which medical management has failed, or for the complications of diverticular disease. Although the majority of cases of diverticulitis will resolve with medical management, approximately 20% of patients with diverticulitis require surgical treatment at some stage. In recent years there has been an increasing trend towards more conservative management options, and considerable debate still surrounds the need for operative intervention, the timing of this surgery, and the appropriate procedure to perform.

Elective surgery

Recurrent diverticulitis has previously been an accepted indicator for elective sigmoid resection, for both symptom control and the prevention of recurrence and more complicated disease. Widely endorsed guidelines, until recently, recommended surgery for any patient who had experienced two attacks of acute diverticulitis requiring hospitalization. Such elective resection in diverticular disease carries not insignificant risks, with morbidity estimated at 25–50% and a mortality of 1–15%, increasing with age. This was justified by historical studies suggesting high rates of recurrence with hospitalization and complicated disease after repeated attacks of diverticulitis. Contemporary studies have challenged this justification, suggesting that the disease in fact follows a more indolent path. The current trend is therefore moving towards more conservative management, and this policy has not so far led to an increase in patients presenting with complicated disease. In addition, there has been a growing recognition that such elective surgery does not always improve the patients' symptomatology and disease recurrence may still occur in 3–13%.

Elective surgery should now only be offered following a full consideration of factors including the patient's age, comorbidities, severity of disease, complications and risk of further episodes. Special cases include patients in remote locations who may have difficulty in accessing medical care for the complications of diverticular disease when they occur, and those in whom repeated hospitalization is unacceptable for work or lifestyle reasons.

Diverticular fistulas may occasionally close spontaneously when the acute inflammatory process settles. More often those not resolving with conservative management require surgical treatment unless patient choice or operative risk prevents this. Patients and clinicians must be aware of the small risk of underlying neoplasia driving the fistulating process rather than a pure diverticular phenomenon. Often this can only be established on histological examination of the excised specimen. The operation should be timed to ensure the patient is nutritionally optimized and inflammation is controlled or quiescent. An attempt at establishing the location of the fistula should be undertaken prior to surgery through appropriate contrast imaging or endoscopic examination. Despite this, at surgery the tract may not be clearly identified and resection of the involved portion of colon may be sufficient to resolve the problem. Primary anastomosis will usually be performed, and the omentum may be mobilized and placed between the bowel and other pelvic organs. The surgery may be technically difficult due to the significant inflammatory mass often associated with such cases, and anatomy may be distorted. Placement of ureteric stents may be considered prior to surgery. Although case series report success undertaking such procedures laparoscopically, their complexity makes this a difficult undertaking.

Emergency surgery

Haemorrhage secondary to diverticulosis is an infrequent cause for emergency surgery, and rarely with symptomatic diverticulitis. As discussed earlier in this chapter, although approximately one-third of patients with bleeding experience severe blood loss this will largely spontaneously settle with only supportive therapy. Only 10–20% of patients will require further intervention. This most commonly takes the form of interventional radiological treatment with mesenteric angiography and embolization of the vessel feeding the bleeding point as discussed earlier in this chapter. Rarely, patients will nonetheless require surgery due to massive recurrent or ongoing bleeding, or failed mesenteric angiography.

The need for surgery in this patient group is related to the ongoing transfusion requirement, with one study indicating that in those receiving ≥4 units of blood 60% will ultimately require surgery. With ≤4 units only 1.5% required surgery. Patients coming to surgery are typically haemodynamically unstable, high-risk cases.

Once an upper gastrointestinal cause is clearly excluded with an oesophagogastroduodenoscopy, laparotomy and on – table colonoscopy may be attempted. The colon is lavaged through the appendix stump in order to clear retained blood and improve the endoscopic view. This may be unrewarding; however, if a bleeding point is clearly identified then a directed segmental colonic resection can be performed with anastomosis or exteriorization of the bowel. If no bleeding point is seen then blind subtotal colectomy can be performed with end ileostomy and mucus fistula. In this situation the patient is often *in extemis* and the surgery has substantial morbidity and mortality.

Stricture or bowel obstruction may result from fibrosis and scarring caused by recurrent episodes of inflammation. Stricturing is seen more frequently than obstruction, which is usually incomplete. Management of these cases depends on the degree of obstruction and urgency with which it presents. With strictures and incomplete obstruction, bowel rest and treatment of the underlying inflammation may be all that is required to get a patient over an acute episode. Full outpatient radiological and endoscopic investigation may then be performed. In cases of complete obstruction, emergency management will be required. In both scenarios, colonic stenting can be considered, either as a temporizing measure and bridge to surgery or as a non-operative option. The procedure is technically more difficult than that for colorectal cancer, because of the longer portion of bowel typically involved. The risk of stent migration is high, and series published so far indicate that complications and need for reintervention are both common. Surgical options include on – table colonic lavage, resection and primary anastomosis, with or without covering ileostomy or alternatively the traditional Hartmann's procedure. Occasionally, small bowel obstruction may develop through its adherence to or involvement in an inflammatory mass. Although CT scanning may help differentiate between primary small bowel obstruction and a secondary cause relating to diverticular disease, exploratory surgery may still be required.

Perforated diverticular disease has traditionally mandated surgery unless clinically futile. Classic dogma taught that Hinchey stage I and potentially stage II diverticular perforations are treated surgically with resection and immediate anastomosis. Resection and diversion via a Hartmann's procedure were reserved for perforated stage III and IV disease. This was based on the theory that an anastomosis in the setting of local infection and/or systemic inflammation is associated with a high risk of anastomotic leak. Evidence is now growing that this may be overtreatment and that such a radical approach may be avoided in many cases. The theory for this comes from the concept of microperforation of the bowel, which subsequently seals. Purulent contamination may therefore not be in direct continuity with the lumen, and may arise from a ruptured interloop abscess.

For Hinchey II and III patients, studies suggest that laparoscopy with copious peritoneal washout with continued antimicrobial therapy may be better treatment provided faecal contamination or free perforation is not seen. If these are seen, conversion to open surgery is still recommended. One prospective multi-institutional study has shown laparoscopic washout is associated with significantly improved outcomes compared with standard laparotomy, with morbidity of 4% and mortality of 3%. Such treatment remains controversial in some quarters, and randomized controlled trials are under way. The surgical options in perforated diverticular disease can be summarized as follows:

- conservative
  - laparoscopic lavage and drainage
  - laparotomy ± suture, drainage and stoma formation
  - exteriorization of sigmoid loop
- radical
  - resection and diversion without anastomosis (Hartmann's procedure)
  - resection and primary anastomosis
  - resection and primary anastomosis with proximal diversionary stoma.

Adapted from ZH Krukowski, in Philips RKS (ed.) *Diverticular Disease* London,UK:Saunders,2010.

When a laparotomy is required, the sigmoid colon should be resected in order to remove the inflammatory focus, rather than simple drainage and washout. A one-stage procedure is preferable in order to avoid the mortality and morbidity associated with further surgery; however, careful patient selection is required for this. A primary anastomosis should only be performed in an adequately resuscitated, cardiovascularly stable patient and where appropriate high-level perioperative care is available. Splenic mobilization should be considered in order to reduce tension on the join. When concerns arise, defaulting to a stoma may be the safest option.

The preference for one-stage surgery has developed partly through increasing experience in performing anastomoses in what would previously have been considered adverse conditions, partly through better patient selection and partly through improved anaesthesia and perioperative care. In parallel with this, studies have shown the high levels of morbidity and mortality associated with a Hartmann's procedure. Stoma complications of over 10% are reported in this setting, and given the elderly population typically affected up to 35% of patients may never have their colostomy reversed due to the risks of further surgery or patient preference. A recent systematic review reported mortality of 9.6% vs 15.1% for primary anastomosis versus Hartmann's resection for perforated diverticular disease.

In this population it is also important to ensure sigmoidoscopy is performed prior to resectional surgery in order to exclude coexistent distal adenocarcinoma, as this may influence the surgery. Sigmoidoscopy can be quickly performed on the operating table so as to avoid any delay to the emergency surgery.

In summary, our understanding of diverticular disease and the optimum treatments for this are in a state of transition. Although diverticular disease is becoming more common, its natural history is still being defined. Several theories regarding the aetiology of the condition exist, and numerous epidemiological risk factors have been identified, however the underlying pathogenesis has not yet been proved. New medical treatments are being investigated, and classically held views regarding the optimum surgical management are being challenged by new paradigms.

Ulcerative colitis

Ulcerative colitis is a distinctive form of inflammatory disease affecting the large intestine. Inflammation of the colon (colitis) has varied aetiology but the various disorders can be grouped as infective or non-infective:

- Infective
  - Virus
    - Cytomegalovirus (CMV)
  - Bacteria
    - *Campylobacter*
    - *Escherichia coli*
    - *Shigella*
    - *Clostridium difficile*
    - *Chlamydia*
    - *Gonococcus*
  - Protozoa
  - Amoebiasis
  - *Cryptosporidium**
  - *Giardia**
- Non-infective
  - Ulcerative colitis
  - Crohn's disease
  - Radiation enteritis
  - Drug-induced colitis

***Especially in immunocompromised patients.**

Ulcerative colitis is a disease confined to the large bowel mucosa. The disease chiefly affects the young and has an equal sex distribution. The annual incidence per 100 000 population is similar for males and females up to the fourth decade of life. As a rule of thumb, it is useful to remember incidences of 10 and 5 per 100 000 for ulcerative colitis and Crohn's disease respectively. The incidence of ulcerative colitis has changed little over the last 30 years, whereas Crohn's disease has increased about fivefold, although this may now be stabilizing and is possibly in decline. The prevalence of ulcerative colitis is about 160 per 100 000 population (compared with about 50 per 100 000 for Crohn's disease). This means that there are around 100 000 people affected in the UK.

Epidemiology and aetiology

Genetics

Between 10% and 20% of affected individuals have a first-degree relative with IBD. There is a concordance within Jewish families, a low incidence in spouses and absence of IBD in families of adopted probands. Crohn's disease and ulcerative colitis can occur in the same family, and the overlap of features of the two diseases (indeterminate colitis) of 10–15% and the change of diagnosis from one to the other in a further 10% may be a feature of genetic heterogeneity. While it has been suggested that both diseases share some similar gene loci with other genes defining each condition, it is noteworthy that there are no reports of mixed Crohn's disease and ulcerative colitis among monozygotic twins.

Extra-alimentary manifestations, including ankylosing spondylitis and primary sclerosing cholangitis, are more common in first-degree relatives of affected *propositi*; both have HLA associations, including HLA-B27 and HLA-B8 respectively. Ulcerative colitis is more common in white people than in black people or Arabs. Whether this is genetic or environmental is unknown. IBD has a low incidence in developing countries.

Environmental factors

The incidence of ulcerative colitis rises about 10 years ahead of Crohn's disease, suggesting environmental influences. There is evidence that NSAIDs can be associated with IBD in humans. It has long been recognized that some patients with ulcerative colitis have a history of infective proctocolitis. Smoking is protective in ulcerative colitis but not in Crohn's disease. It also appears to be true for pouchitis. Data are conflicting on the influence of oral contraceptives, and most of the information relates to Crohn's disease. No causative dietary factor has been identified in humans. However, lactose intolerance can accompany ulcerative colitis, although this is rare.

Pathogenesis

Inflammation is confined to the large intestine, which includes the colon, rectum and upper anal canal. The mucosal columnar glandular epithelium extends into the anal canal to the anal transitional zone, which varies in longitudinal length from a few millimetres to over a centimetre. The anatomical extent of ulcerative colitis varies from involvement of the upper anal canal and rectum alone (proctitis) to the colon more proximally (proctocolitis). The rectum is always involved for all practical purposes, although relative rectal sparing can occur in patients receiving local anti-inflammatory treatment. A spared rectum not associated with local treatment should raise the suspicion of Crohn's disease. Backwash ileitis occurs only in cases with colonic extension to the ileocaecal junction. Anal disease occurs in about 10% of cases coming to proctocolectomy. The lesion is usually minor, e.g. a low fistula or fissure. Rectovaginal fistula can occasionally occur in ulcerative colitis.

The inflammation in the colon and rectum is diffuse without intervening normal mucosa. Ulceration causes bleeding and in patients with severe disease the inflammatory exudate results in

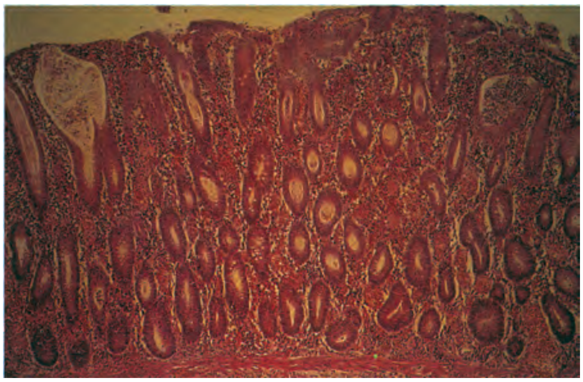

Figure 30.31 Histological appearances of ulcerative colitis. Note the crypt abscesses.

loss of water, electrolyte and protein which may be as great as 200 g per 24 hours (Figure 30.31).

Clinical presentation

At presentation, approximately 50% of patients have disease confined to the rectum (proctitis). In 30% this extends to the left colon (proctosigmoiditis) and in a further 20% disease extends beyond the splenic flexure (extensive colitis). Symptoms are local and general. The severity of the former and the presence of the latter depend largely on the anatomical extent of the disease. Ulcerative colitis is characterized by exacerbations and remissions. Bloody diarrhoea with urgency is the hallmark of colitis.

Proctitis

Symptoms include bleeding and mucus secretion. Sometimes constipation occurs but more often there is increased frequency of defecation. Rectal irritability may result in urgency of defecation. Systemic symptoms are very uncommon. Patients do not suffer from disturbances of growth, and only rarely from extra-alimentary manifestations or subsequent cancer. There is a tendency for proctitis to extend proximally with time.

Proctosigmoiditis and extensive colitis

Proximal extension to the left colon and more proximally leads to worsening local symptoms and systemic disturbances in some cases. Urgency is the most incapacitating local symptom. When severe, patients may have warning of impending defecation of a few seconds only. In such cases, urge incontinence can occur. Severe symptoms often dominate the patient's life and seriously affect work and family life. The protein-losing enteropathy may lead to malnutrition with loss of lean body mass and anaemia. Retardation of growth in children may be a feature of extensive colitis. In acutely ill patients, water and electrolyte loss may cause hypovolaemia and breakdown of the mucosal barrier may lead to toxicity.

Exacerbations may be precipitated by anxiety or stress but usually there is no recognizable causative factor. The disease may be of the acute relapsing type, with acute episodes interspersed by periods of complete resolution. Alternatively it may take the form of persisting chronic disease. Such patients may develop acute exacerbations that settle only partially on treatment. Patients with extensive disease are more likely to have associated extra-alimentary manifestations and are at greater risk of developing malignancy. These complications can occur in patients with disease confined to the left side of the colon but are much more frequent in extensive colitis.

Acute presentation

About 5% of patients present with acute severe colitis as the first manifestation of the disease. The patient will be ill with severe local symptoms, weight loss, anorexia, and water and sodium depletion. Intensive medical treatment has a high chance (70%) of inducing remission but when unsuccessful urgent or semi-urgent surgery will be necessary. Acute severe colitis may progress to toxic dilatation recognized by distension of the colon to a diameter greater than 6 cm on a plain radiograph. Perforation is a rare but serious occurrence with a mortality still approaching 40%. Rarely deep ulceration (usually in the rectum) may cause severe bleeding.

Extra-alimentary manifestations of ulcerative colitis

Up to one-third of patients with ulcerative colitis will develop at least one extra-alimentary manifestation during the course of the illness. These can be divided into those related or not to disease activity. Amyloid or hypertrophic osteoarthropathy are rare and are the result long-standing chronic illness.

Arthropathy

Arthropathy is the commonest extra-alimentary manifestation. It can be divided into three broad groups.

Activity - related polyarthropathy occurs in up to 20% of patients and is more likely in those with extensive disease. It affects predominantly the large joints of the limbs, knees being the most common. The arthropathy is fleeting and asymmetrical and is rheumatoid factor negative. It disappears when medical treatment induces a remission or after proctocolectomy. It can develop in patients with pouchitis after restorative proctocolectomy.

Ankylosisng spondylitis is an axial arthropathy involving the sacroiliac joints and one or more vertebrae and occurs in up to 5% of patients. The majority of such cases are HLA-B27 positive. The disease is unrelated to the activity of colitis and does not respond to proctocolectomy. There may be a genetic basis.

Asymptomatic sacroileitis is an arthropathy limited to the sacroiliac joint and is HLA-B27 negative. It occurs more frequently than ankylosing spondylitis and is also unaffected by treatment for the colitis.

Liver

Ulcerative colitis - associated hepatic and extrahepatic disorders occur in up to 5% of cases, predominantly in those with extensive colonic involvement. Fatty degeneration is common, but has no obvious clinical importance. Parenchymal liver disease of the chronic active hepatitis type and cirrhosis can occur. The latter may lead to portal hypertension.

Primary sclerosing cholangitis is more often seen in ulcerative colitis than in Crohn's colitis. The disease is characterized by a fibrous inflammatory reaction within the biliary tree leading to multiple intra- and extrahepatic stenoses. The diagnosis is made on endoscopic retrograde cholangiopancreatography or MRI. There is no apparent relationship between duration of disease and disease activity, although patients with primary sclerosing cholangitis undergoing restorative proctocolectomy have a higher subsequent incidence of pouchitis and dysplasia in the ileal pouch mucosa. Treatment by steroids, colectomy or antibiotics is ineffectual and ultimately the disease progresses to liver failure. Such patients may be considered for liver transplantation.

Cholangiocarcinoma is a rare association with ulcerative colitis. There may be an induction period of many years and the risk appears to continue even after proctocolectomy.

Skin

Erythema nodosum is the commonest cutaneous manifestation of IBD. It occurs more often in Crohn's disease. The condition is activity related. Pyoderma gangrenosum is more often associated with ulcerative colitis. It usually occurs in the lower limb as a circumscribed area of erythema with a punched-out ulcerated centre. Lesions may be multiple and occasionally are very extensive. Proctocolectomy is associated with healing in about 50% although this may take weeks to months.

Eyes

Uveitis is rare and is not related to disease activity. The condition can lead to scarring with visual impairment and ophthalmological management is essential. Episcleritis is activity related and occurs more often in Crohn's disease. It does not lead to chronic changes.

Cancer

The occurrence of malignant transformation has been known for years but it was not until 1967 that dysplasia was recognized as a histopathological marker for impending or actual malignancy. Ulcerative colitis should therefore always be considered when large bowel cancer presents at an early age. The incidence of cancer depends on the duration of the disease. This is estimated to be less than 1% within 10 years of onset, increasing to 10–15% in the second decade and to over 20% in the third. As a rule of thumb after 10 years of colitis the incidence of colorectal cancer increases by 1% per year (Figure 30.32).

Colonoscopic surveillance relies on the identification of flat dysplasia or a dyspasia - associated lesion or mass. There is general agreement among pathologists on the criteria for its diagnosis. The presence of low-grade dysplasia is as likely as high-grade dysplasia (54% vs 67%) to be associated with an already established cancer.

Cancers can be missed by colonoscopic surveillance programmes. The American College of Gastroenterology Practice Parameters Committee has recommended colonoscopy annually or every 2 years with multiple biopsies taken at 10 cm intervals through the colon and rectum. Review of the blopsies by an experienced histopathologist is essential.

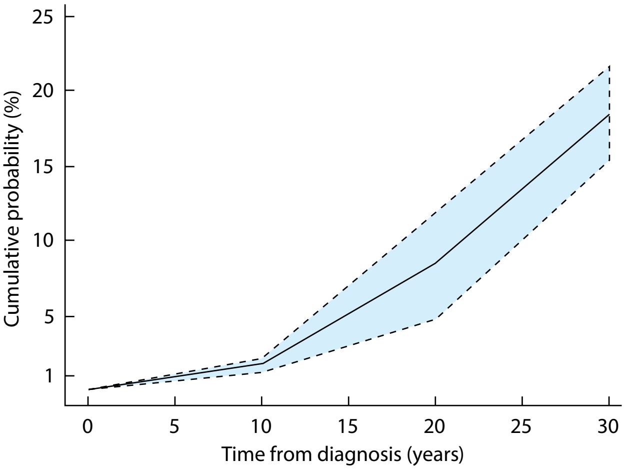

Figure 30.32 Risk of developing cancer in ulcerative colitis among 194 studies of 54, 478 patients. (Adapted from Eaden *et al.*, Gut 2001; 48:526–35.)

Investigation

In the tropics, infective causes constitute the vast majority of causes of colitis. In temperate regions infective causes may occur in hospitals and long-stay institutions. The diagnosis is made by histopathological examination of biopsy material taken during endoscopy having excluded microbiological causes. Endoscopy will determine the extent of inflammation in the assessment of severity.

Microbiology

A specimen of stool must be sent for microbiological examination. If amoebiasis is suspected, the specimen should be examined in the laboratory within a few hours. In addition, diagnosis of amoebiasis requires a biopsy to demonstrate cysts. *Shigella, C. difficile* and *Campylobacter* infection should be excluded. These may occur in epidemics in institutions with a significant mortality in frail elderly patients. The microbiologist should be warned on the request form that these could be present.

Proctitis can be caused by gonorrhoeal and chlamydial infection. The inflammation is catarrhal and consists of an erythematous flare associated with a purulent exudate. It rarely extends proximally beyond a few centimetres from the anal verge. When suspected, rectal, urethral and vaginal swabs should be taken. Again the microbiologist should be forewarned. Opportunistic infection may cause proctocolitis in immunocompromised patients (e.g. those with human immunodeficiency virus infection) or those on immunosuppressive drugs. Examples include cytomegalovirus, *Mycobacterium avium-intracellulare* and cryptosporidia.

Endoscopy

Loss of the vascular pattern (the submucosal vessels seen through the transparent mucosa) is the most sensitive sign of inflammation. This is due to oedema of the mucosa which makes it opaque. Oedema also causes fine granularity in which there is a delicate regular stippled appearance of the mucosal surface. More severe changes include erythema, contact bleeding and frank ulceration. Where previous acute attacks have been followed by repair, mucosal regeneration nodules (coarse granularity) or pseudopolyps may be seen. Pseudopolyps represent tags of mucosa that have been partially detached during the active episode and remain as projections after healing of ulceration. Rigid sigmoidoscopy will only visualize the rectum. Colonoscopy allows assessment of the proximal extent of the disease.

Histopathology

Histopathological examination of a mucosal biopsy is the basis of diagnosis.

Biopsy technique

A biopsy is obligatory and is most easily obtained during rigid sigmoidoscopy. Colonoscopy used for surveillance allows multiple biopsies to be taken. Perforation and bleeding are potential complications. The patient must be asked whether anticoagulants or immunosuppressive drugs are being taken before a biopsy is performed. The biopsy taken during rigid rectoscopy itself should be obtained with forceps with a circular cusp that minimizes the depth of penetration. The optimal site is about 7 cm from the anal verge in the posterior quadrant of the rectum. Adequate vision during rectoscopy must be assured and the jaws of the forceps are firmly closed, taking a bite of mucosa and submucosa. After the biopsy has been taken, the site must be inspected for bleeding. If this persists, a topical solution of epinephrine (adrenaline) 1 in 1000 soaked in a small swab should be applied to the biopsy site. The biopsy should be oriented onto a piece of absorbent paper and placed in formalin (10%).

Histopathological features

Active disease

In active disease, there is mucosal thickening with infiltration of the lamina propria by neutrophils, plasma cells, lymphocytes, eosinophils and mast cells. Mucin within goblet cells is discharged so that these are less evident or absent (goblet cell depletion). The degree of neutrophil infiltration is the best histopathological marker of severity. In mild disease, neutrophils are confined to the lamina propria. Extrusion of neutrophils into the crypt lumen forms a crypt abscess, the number of which correlates with the severity of disease. Mucosal ulceration is partly the result of rupture of crypt abscesses leading to mucosal destruction. Damage to the crypt basal epithelium leads to loss of crypts. Attempts at regeneration may be mistaken for dysplasia but the presence of more normal cells towards the luminal surface allows these to be distinguished. There may be branching of crypts owing to regeneration following crypt epithelial damage.

Acute severe colitis

Progression of these acute changes occurs in cases with acute severe colitis. Ulceration can be very extensive, leaving large areas of exposed muscularis propria covered with granulation tissue. This may be associated with thinning of the musculature and colonic dilatation. Inflammation may be transmural and fissure formation may be seen. Colitis in remission may leave a distorted architectural pattern with crypt depletion. Mucosal cells that remain often regain normal function and show retained mucin as identifiable goblet cells. A chronic inflammatory cell exudate in the lamina propria is likely to be present, although this may be very mild in patients in remission for long periods. Paneth cell metaplasia indicates episodes of previous colitis.

Table 30.7 Histopathological distinction between ulcerative colitis and Crohn's disease

	Ulcerative colitis	**Crohn's disease**
Macroscopic		
Distribution	Colon and rectum	Gastrointestinal tract
Rectum	Involved	Often spared
Anal disease	Rare	Common
Malignant risk	10% at 20 years	Probably similar in large bowel disease
Intestinal fistula	Never	Common
Stricture (non-neoplastic)	Rare	Common
Microscopic		
Bowel wall involvement	Mucosa and submucosa	Full thickness
Granulomas	None	60–70%
Mucus secretion	Impaired (goblet cell depletion)	Slightly impaired
Fissuring	Absent	Common
Crypt abscess	Common	Rare

Ulcerative colitis/Crohn's disease

Diagnostic difficulties in differentiating ulcerative colitis and Crohn's disease have been recognized for many years. The pathological criteria distinguishing them are shown in Table 30.7.

Indeterminate colitis

In some patients insufficient numbers of these diagnostic attributes are present or there is considerable overlap and atypical features are seen. Thus it may be impossible for the pathologist to separate the two diseases, which may be reported as unclassified colitis or as unclassified colitis with additional indication of the possible or probable presence of Crohn's disease or ulcerative colitis. In about 10% of cases, however, the pathologist will be able to state only that the colitis is indeterminate.

Indeterminate colitis is not a disease entity. It is a term which indicates that the histopathologist is unable to come to a firm diagnosis owing to the presence of features of both conditions. Usually the dilemma arises in emergency colectomy specimens where severe inflammation may be combined with features of ulcerative colitis and Crohn's disease.

In trying to resolve the diagnostic dilemma more biopsies should be taken. If the patient has had a colectomy for acute disease, then these will come from the rectal stump which may have already developed diversion proctitis making the histopathologist's task more difficult. The small bowel should be examined by endoscopy or radiology which if abnormal is suggestive of Crohn's disease as would be the presence of an anal lesion.

When histopathological, radiological and clinical features are considered together, patients with indeterminate colitis can usually be judged to incline more to Crohn's disease or ulcerative colitis. Where they cannot, the natural history tends to incline to that of ulcerative colitis.

Radiology

A plain abdominal radiograph is the most useful means of identifying colonic dilatation. There has been a movement away from tubular contrast radiology to CT. The instant barium enema is now rarely used although it gives an excellent record of the extent of the disease in most cases.

Treatment

Best care is likely to be achieved by a multidisciplinary team including medical staff, specialist nurses, nutritionists and stoma-therapists with social and psychological support. Collaboration between gastroenterologist and surgeon is essential and should include patient sharing where appropriate, joint outpatient consultations for difficult cases, and early involvement of the surgeon in acute disease.

Medical treatment

Medical treatment involves bed rest and the correction of water and electrolyte depletion by intravenous infusion. Severely anaemic patients should be given blood. The patient should be encouraged to eat a high protein and calorie diet. Intravenous nutrition may be indicated in severely malnourished patients, as judged by a decrease in lean body mass and serum albumin.

Intravenous prednisolone (60 mg daily) and an H_2-receptor antagonist or a proton pump inhibitor to protect against upper gastrointestinal ulceration are given. Ciclosporin has been reported to induce remission in over 50% of patients unresponsive to steroids but early relapse may occur, resulting in the same clinical situation within a short period.

More recently, a number of studies have reported the use of biological agents for the treatment of acute ulcerative colitis. Infliximab (Remicade Centocor, Malvern, PA), a chimeric (75% mouse, 25% human) anti-tumour necrosis factor (TNF)-α monoclonal antibody, and Adalimumab (Humira, Abott), a humanized anti-TNF antibody, are currently used to modulate the proinflammatory processes central to the pathogenesis of IBD. In a study of 30 patients with active ulcerative colitis treated with infliximab between 2000 and 2006 at Oxford, 53% of patients came to colectomy at a median time of 140 days after their first infusion (range 4–607). Of those avoiding colectomy, only 17% sustained a steroid-free remission. The role of immunotherapy in the acute setting remains to be established in a number of randomized controlled trials.

Patients with severe acute colitis require admission to hospital. Initial treatment is medical but about 30% of patients will come to surgery. Surgery is absolutely indicated in cases with acute toxic dilatation or perforation.

Monitoring is essential to assess improvement or deterioration. The pulse rate, temperature and blood pressure are regularly recorded. The patient should be weighed on admission and twice weekly thereafter. Blood should be sent for haemoglobin, albumin and electrolyte estimations. A stool chart is essential. This should record every defecation with an assessment of volume and consistency of stool and the presence or absence of blood on each occasion. The abdomen should be examined regularly. Distension suggests the possible development of toxic megacolon. A plain radiograph will allow assessment of the colonic diameter. Abdominal tenderness and rigidity suggests local or general peritonitis. The presence of intramural gas on the plain abdominal radiograph is a sign of imminent perforation and is therefore an indication for immediate surgery.

Unresponsiveness to medical treatment in acute colitis

Failure to respond to medical treatment should be recognized early. The gastroenterologist and surgeon should confer at least daily to decide whether there has been improvement, stagnation or deterioration. Deterioration despite adequate medical treatment should be an indication for surgery. Stagnation over several days with no sign of improvement should also be an indication for operation.

Clinical indicators that surgery is likely to be necessary at the time of admission include a frequency of defecation of over 10 times per 24 hours with the passage of blood at every defecation attempt, low albumin, low haemoglobin and a fall in lean body mass of more than 10%. Previous acute attacks, poor general health and social circumstances affected by the disease should be taken into account. A significant history of chronic illness and social incapacity should sway the decision in favour of surgery.

Medical treatment of proctitis

Most patients are satisfactorily treated medically by a combination of steroids and 5-ASA preparations. The former is intended to induce a remission, the latter to maintain a remission once achieved. Both can be given as suppositories or as an enema, the choice depending on the proximal extent of disease. Steroid preparations such as budesonide have a lesser tendency for absorption. An oral 5-ASA preparation should also be prescribed from the beginning. Modern 5-ASA drugs (Asacol, Pentasa and Balsalazide) no longer contain sulphonamide, which was responsible for some of the side effects of salazopyrine. They are formulated to protect the aspirin from degradation before it arrives in the colon. Proctitis refractory to this treatment may respond to other preparations, including bismuth, nicotine and witchhazel. Rarely, patients with persisting severe symptoms may require surgery.

Megacolon, perforation and bleeding

Megacolon is an indication for surgery (Figure 30.33). If signs of peritonism are present, operation should not be delayed. When surgery is performed prior to perforation, the reported mortality is 2–8%. Perforation is a grave development with a mortality around 40%. It may be silent in a patient on large doses of steroids, and may become evident only by the presence of free gas on the plain abdominal radiograph. Its occurrence without megacolon is rare and should raise the possibility of Crohn's disease. Severe bleeding usually arises from ulceration in the rectum.

Medical treatment of chronic proctocolitis

Medical management includes anti-inflammatory, nutritional, symptomatic and psychological treatments.

Prednisolone is given in an initial dose of 40 mg, gradually reducing this as remission occurs over the next few weeks. Azathioprine can be tried in patients who do not respond to steroids or in those who are steroid dependent in the hope of avoiding long-term steroid treatment. Ciclosporin can be effective in inducing remission in patients suffering from acute

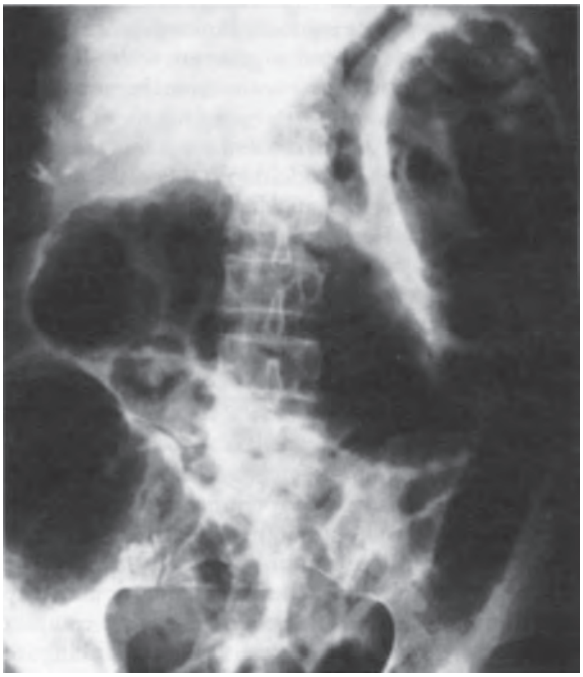

Figure 30.33 Plain radiograph appearances of toxic megacolon.

severe colitis but its role in chronic disease is not established. The nutritional state should be monitored. There is no specific diet that influences the activity of the disease but a high protein and calorie intake should be encouraged. Specific replacement treatment such as iron may be necessary. Antidiarrhoeal agents including codeine phosphate and loperamide are usually effective in reducing frequency and urgency. Maximal doses are 60 mg four times daily and 8 mg four times daily respectively. Lomotil (atropine and diphenoxylate) is occasionally effective where there has been a poor response to the others. Bone densitometry should be carried out where steroid medication has been prolonged.

Unresponsiveness to medical treatment in chronic colitis and surgical indications

Most patients requiring surgery have extensive disease. They are those most likely to have severe local symptoms and systemic illness. There is a greater risk of acute severe colitis and malignant transformation. Very occasionally, a patient with distal disease may require surgery, usually because of severe local symptoms. The indications for elective surgery include:

- unresponsiveness to medical treatment
- retardation of growth in the young
- malignant transformation.

Unresponsiveness to medical treatment

This indication can be further divided into various clinical categories, as follows.

Chronic disease

The patient continues to suffer from systemic and local symptoms despite adequate medical treatment. Chronic anaemia associated with general weakness, poor energy levels, amenorrhoea and extra-alimentary manifestations may leave the patient unable to lead a normal life. Patients may have experienced multiple hospitalizations, periods off work, disruption of family life and education and other social effects of chronic illness. Patients who have never experienced a complete remission from medical treatment are included in this group.

Steroid dependence

A response to steroids may be maintained only by continuing the therapy with relapse on withdrawal. If alternative medication such as immunosuppression is unsuccessful, then surgery is indicated unless there are particular reasons against.

Recurrent acute exacerbations

The decision for surgery will depend on the frequency and severity of attacks. Surgery during an acute attack will usually take the form of a colectomy with ileostomy. A decision taken during remission may allow an elective definitive procedure such as restorative proctocolectomy to be performed as the first stage procedure.

Severe symptoms

The patient may be systemically well but severely inconvenienced by frequency and urgency of defecation particularly if associated with urge incontinence.

Extra-alimentary manifestations

Not all symptoms will respond to removal of the large bowel; liver manifestations and sacroiliitis do not. However, the activity-related polyarthropathy does respond, as will some cases of pyoderma gangrenosum, although the latter may improve only slowly over several months.

Growth retardation

Ulcerative colitis, if extensive, has an inhibitory effect on growth and the development of secondary sexual characteristics. Steroid medication itself leads to early fusion of epiphyses, resulting in permanent stunting of growth. Patients in this category are usually under the care of a paediatric expert in the assessment of growth. However, within the years of puberty a delay in surgery may occur, partly because of the antipathy of the paediatrician and/or patient (or parents) to an ileostomy.

Malignant transformation

The presence of high- or low-grade dysplasia or an established invasive tumour is an indication for surgery. The surgical technique should be as though invasion had occurred since this can be determined only by examination of the resected specimen.

Surgical treatment

Acute colitis (emergency surgery)

Surgery has a major role in the management of acute colitis. The need for surgery is greatest during the first year after onset of the disease. The indications and their relative frequency are shown in Table 30.8 and Figure 30.34, respectively.

Colectomy with ileostomy and preservation of the rectum

This is the operation of choice for acute severe colitis. For all surgery for ulcerative colitis the reversed Trelendenberg position with the legs raised (Lloyd-Davies) should be used,

Table 30.8 Indications for emergency surgical intervention for ulcerative colitis 1976–1990

Main reason for surgery	No. of patients
Unresponsiveness to medical treatment	71
Toxic dilatation	23
Perforation	9
Bleeding	2
Other	1
Total	106

From Melville *et al.* *Gut* 1994;**35**:1076–80, with permission.

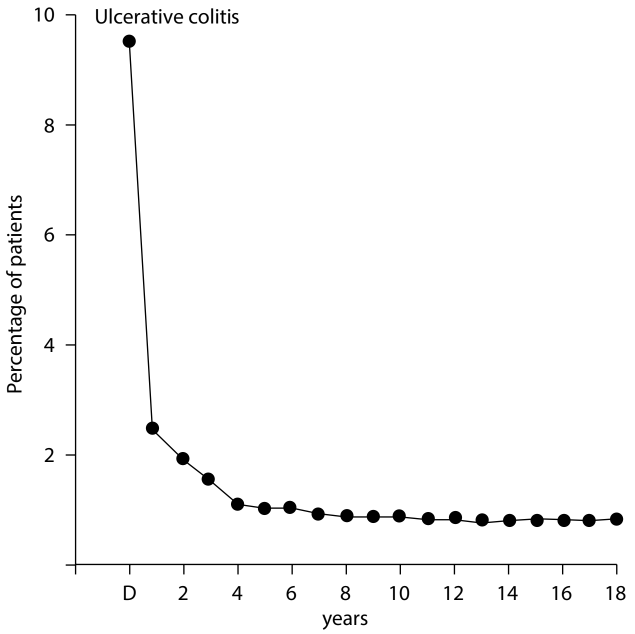

Figure 30.34 Colectomy rates in progressive years following the diagnosis (D) of ulcerative colitis.

thereby allowing access to the rectum. The bladder is routinely catheterised. It is helpful to insert a proctoscope before starting to drain the rectum and deflate the bowel.

Ileostomy trephine and incision

When an ileostomy forms part of the procedure, the trephine should be made before opening the abdomen. For open colectomy this should be midline. This can be limited to 7 cm or less in a thin patient. A paramedian incision is no longer appropriate. For laparoscopic colectomy a small incision is made to remove the specimen. It also allows a manual port if hand-assisted laparoscopy is used.

On opening the abdomen, care must be taken to avoid perforation. Where adhesions have formed between the colon and the parietes, dissection should be made within the latter.

Operative steps

These are discussed below.

- Mobilization of the right colon. The surgeon stands on the patient's left side.
- Division of the bowel. The bowel is divided at the ileocaecal junction before proceeding further. This allows control of the right colon manually to allow safe division of the ileocolic and right colic vessels, by avoiding tension.
- Division of vessels of the transverse colon.
- Mobilization of the left colon. The surgeon moves to the other side of the table to do this.
- Mobilization of the splenic flexure. The splenic flexure is often drawn down owing to shortening of the bowel due to the disease process and may be very easy to mobilize.
- Division of the sigmoid.

The level of division should allow sufficient length of distal bowel to be able to exteriorize it through the anterior abdominal wall whether a mucous fistula is formed or not. Division at the level of the peritoneal reflection leaves a distal stump that is too short to be exteriorized in the uncommon event of breakdown of the distal suture line and also makes identification of the rectum at a subsequent operation difficult. A long rectosigmoid stump should therefore be aimed for unless it is necessary to remove the rectum in the case of severe bleeding (Figure 30.35).

Mucous fistula formation

Although leakage of the distal closure suture line is uncommon (<5%), the creation of a mucous fistula should be considered in patients in poor condition with malnutrition and where the bowel wall is too diseased safely to take sutures. The ileostomy and mucous fistula should be brought out sufficiently far apart to allow a stoma appliance to be placed over each without interference. Placing the mucous fistula in the contralateral iliac fossa achieves this. Some surgeons prefer to close the stump and leave it in the subcutaneous fat deep to the abdominal wound.

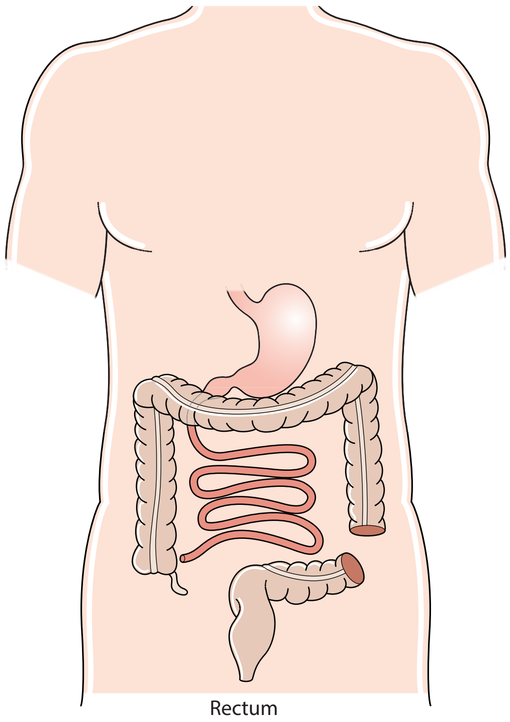

Figure 30.35 Emergency colectomy: level of division of the sigmoid allowing adequate mobility for exteriorization.

Postoperative outcome

In the immediate postoperative period, it is advisable to drain the rectum (particularly if the stump is closed) by daily insertion of a proctoscope. Complications include intestinal obstruction and sepsis. Obstruction usually resolves spontaneously. Sepsis may be due to an intra-abdominal collection or leakage from a closed rectosigmoid stump. This will usually require reoperation and exteriorization of the distal bowel if possible. Rarely, rectal excision preserving the anal canal will be necessary. Occasionally, persisting inflammation in the rectal stump may be so severe despite local treatment that rectal excision is required.

Recovery usually occurs within a few weeks to a couple of months, during which steroids and other medication are gradually withdrawn. Health and self-confidence are restored allowing return to work or education. The timing of any subsequent operation is determined by the patient but should not be before 3 months.

Mortality ranges from <1% to 5% from specialist centres in the UK, Denmark and the USA. Recent linkage analysis of 8245 patients with ulcerative colitis having a first hospital admission for ulcerative colitis of more than 4 days in England between 1998 and 2000 indicate that the mortality up to 2003 (3 years) is lower after an elective (2.2%) or emergency procedure (3.2%) than if no operation is carried out (7.4%). If substantiated these data suggest that the threshold for surgery may be too high. There is evidence that mortality is higher in smaller, low - volume hospitals.

Chronic colitis (elective surgery)

There are four surgical options:

- colectomy with ileostomy and preservation of the rectum
- conventional proctocolectomy and permanent ileostomy
- colectomy and ileorectal anastomosis
- restorative proctocolectomy and ileal reservoir.

All these operations involve total removal of the colon (Figure 30.36). There is no place for partial colectomy, even in cases with a normal right colon, where experience has shown a high frequency of recurrence in the remaining colon. In patients having a permanent ileostomy, a Kock pouch (see below) may be possible in certain circumstances.

Colectomy with ileorectal anastomosis should be considered only where the rectum is minimally inflamed and distensible and where there is no evidence of dysplasia anywhere in the large bowel. Most patients do not fulfil these criteria, leaving the alternative of conventional or restorative proctocolectomy. The latter is excluded, however, if the anal sphincter is inadequate or the anus is diseased. Much will depend on the wishes of the patient. Here, it is essential for the clinician to give detailed information on the morbidity, function, late complications and likely duration of treatment of the various options. Input from the stomatherapist and patient-support groups should be obtained. The introduction of restorative proctocolectomy has resulted in this operation being the most commonly used with over 80% of patients requiring elective surgery.

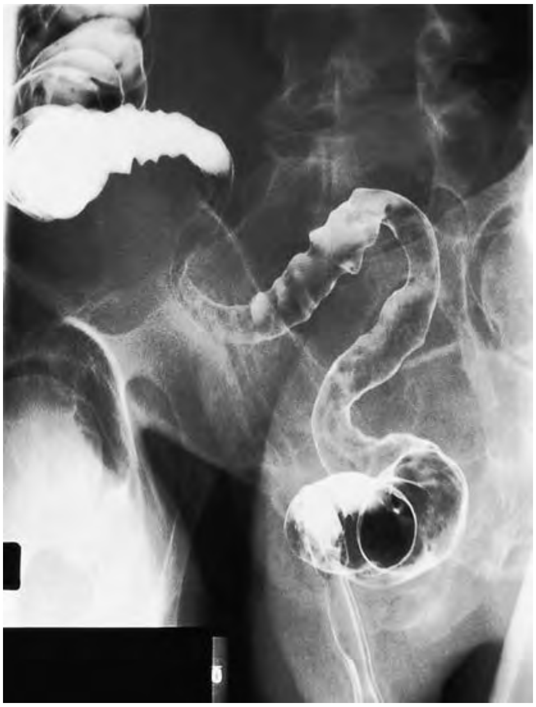

Figure 30.36 Barium enema appearances of longstanding ulcerative colitis.

Colectomy with ileostomy and preservation of the rectum

This operation also has a place in elective treatment. For patients too unfit for a restorative proctocolectomy it may be preferable to carry out an initial colectomy. Besides the advantages of rapid return to health (see above), the experience of an end-ileostomy is useful to the patient when considering further surgery. Where the diagnosis of ulcerative colitis is in doubt, a colectomy gives the histopathologist more material to make a diagnosis. Dysplasia is extremely rare within 10 years of the onset of colitis and there is, therefore, no hurry for reoperation in most cases. All of the options discussed below can then be considered.

Conventional proctocolectomy with permanent ileostomy

The introduction of the everted ileostomy established this operation as the standard procedure for ulcerative colitis until the description of restorative proctocolectomy. Ulcerative colitis is cured, with the only disadvantage being a permanent ileostomy.

Indications

The indications include rectum and anus not suitable for restorative procedure, i.e.:

- inadequate sphincter
- cancer in the low rectum
- patient preference.

The patient should appreciate the possibility of ileostomy-related complications requiring further surgery and delayed healing of the perineal wound. These are offset by those of pelvic sepsis and long-term developments such as pouchitis after restorative proctocolectomy.

Operative steps

Creating the ileostomy trephine before the midline incision and colectomy have already been discussed. Where a carcinoma or dysplasia is present a conventional anatomical dissection total mesorectal excision (TME) should be carried out. The majority of patients do not have neoplastic transformation and, in these, the rectum may be removed by close (perimuscular) dissection to minimize the incidence of pelvic nerve damage, which might cause urinary or sexual dysfunction although there was no statistically significant difference in a non-randomized comparison of perimuscular and conventional dissection. Whatever technique is used, dissection should be kept behind Denonvilliers' fascia anteriorly and close to the rectal wall laterally where the autonomic pelvic nerves are mostly at risk. In the absence of carcinoma in the low anorectal region, the anal canal should be removed using the intersphincteric technique. Good ileostomy technique includes preparation of the mesentery and its fixation to the peritoneum of the anterior abdominal wall. The terminal 5 cm of ileum are perfused by the marginal vessel after division of the ileocolic artery and vein. The stoma itself is completed by mucocutaneous interrupted sutures. It will evert spontaneously; a projection of 2.5 cm is ideal.

Postoperative outcome

Obstruction may occasionally require reoperation but usually settles spontaneously. Rarely it is due to herniation of the small bowel into the space lateral to the ileostomy. A haematoma in the cavity left by the rectum may become infected. Drainage with resolution of the acute problem may be followed by a perineal sinus. This may require subsequent surgery with curettage and rarely in refractory cases the need for a perineal myocutaneous rectus abdominus flap. Delayed healing of the perineal wound at 6 months occurs in 10–20% of cases

Ileostomy complications are common. Stricture formation, prolapse and retraction may cause difficulty in maintaining a water - tight appliance, as may parastomal herniation. Corrective surgery is often required, with a reported cumulative ileostomy revision rate of around 25% at 5 years. It is usually possible to carry out a local revision, but in some cases, particularly with herniation, resiting is required. This is a major undertaking.

The continent ileostomy

Kock developed this operation (Figure 30.37) initially for bladder replacement and then adapted it to create a continent abdominal intestinal stoma. The procedure still has a place in patients in whom the anal sphincter has been removed. A reservoir is constructed from 30 cm of the terminal ileum and the most distal 15 cm of small bowel are invaginated into the reservoir to form a nipple valve. This maintains continence and the reservoir is emptied several times per day by catherization of the abdominal stoma using a wide - bore tube.

Early complications include leakage from the reservoir causing peritonitis or fistulation. The most important late complication is subluxation of the nipple valve. It is suggested by the onset of incontinence of the stoma and difficulty in inserting the catheter. Contrast radiology may show partial or complete prolapse of the valve. Valve slippage occurs in 17% to over 40% of cases, and is the most common cause of failure. Reported fistula rates range from 10% to 26%. Of 330 patients treated at a single institution between 1974 and 2001, pouch survival at 10 and 20 years was 87% and 77%, respectively. Patients with indeterminate colitis or Crohn's disease were 4.5 times more likely to lose the pouch than those without, although in one series the cumulative 10 year recurrence rate in 49 patients with Crohn's disease was 48%, with excision of the pouch required in only eight.

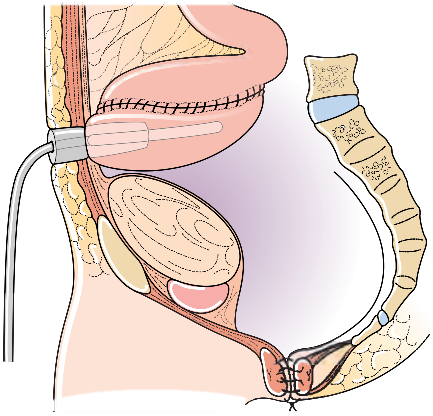

Figure 30.37 The Kock continent colostomy.

Long-term continence rates of over 90% have been reported. The cumulative 4 year incidence of pouchitis is around 40%. Dysplasia has been reported in three of 40 patients followed for a median of 30 years. One case of carcinoma in the pouch has been reported.

Continent ileostomy may be indicated in motivated patients in whom restorative proctocolectomy is not an option and in patients who already have a permanent ileostomy and desire an improved quality of life. It has also been carried out after failure of restorative proctocolectomy.

Colectomy with ileorectal anastomosis

Indications

Colectomy with ileorectal anastomosis is a well-tolerated one-stage procedure. Before the introduction of restorative proctocolectomy it was the only procedure which avoided an ileostomy being used in 10% to over 80% of patients according to the preference of the surgeon. Since then, its incidence has fallen to below 10%. The indications are as follows:

- a non- or mildly inflamed rectum with good compliance
- absence of dysplasia anywhere in the large bowel
- adequate anal sphincter
- availability of the patient for follow-up
- presence of disseminated colonic carcinoma with relative rectal sparing.

The patient must also be prepared to be followed by annual rectoscopy with biopsy owing to the risk of malignancy in the rectal stump which is about 5% at 20 years. If this is not possible then the operation should not be advised.

Operative steps

The technique is identical to colectomy with ileostomy up to the point of removal of the specimen. The upper rectum is very accessible for manual or stapled anastomosis (Figure 30.38).

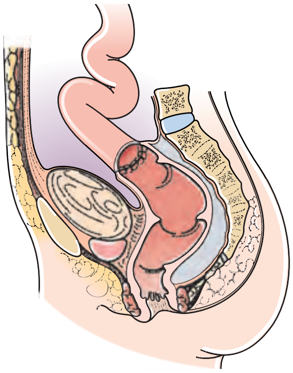

Figure 30.38 Colectomy with ileorectal anastomosis.

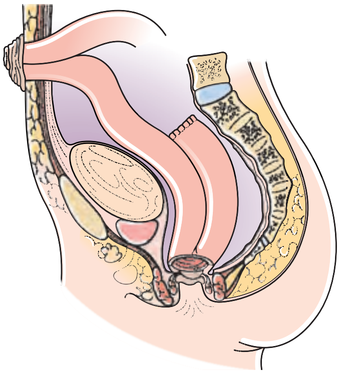

Figure 30.39 Ileal J-pouch with proximal defunctioning ileostomy.

Postoperative outcome

The operation is a compromise since there is potentially active disease in the rectum. This can lead to failure because of persisting inflammation causing poor function or the development of malignancy. The results demonstrate a low mortality and morbidity but considerable differences in failure requiring removal of the rectum. There were 12 deaths among 22 cancers that developed during follow-up in a series of 384 patients.

Patients who fail are candidates for rectal excision with permanent ileostomy or restorative proctectomy, provided that any cancer in the rectum can be adequately cleared without having to sacrifice the anal canal and provided there is no dissemination.

Restorative proctocolectomy with ileal reservoir

The strategy of complete removal of the large bowel with sphincter preservation was first described fully by Ravitch and Sabiston. The 'straight' ileoanal anastomosis was adopted by a few surgeons at the time and the functional results were subsequently reviewed by Valiènte and Bacon. Function was often poor due largely to urgency and frequency.

The introduction of the continent ileostomy showed that a small bowel reservoir could function in humans and this led Parks to combine this with his own endoanal anastomotic technique to create the ileoanal ileal reservoir procedure (Figure 30.39). Capacitance of the neorectum is inversely related to frequency, irrespective of whether the neorectum is constructed using straight ileum, or an ileal or colonic reservoir

Indications

The only reason for the operation is to avoid a permanent ileostomy. A conventional proctocolectomy gives excellent results except for this. Where there is no medical objection, the choice lies between a restorative or conventional proctocolectomy and is almost entirely the patient's to make. This is possible only if the disadvantages are fully discussed. These include failure and complication rates, total treatment time, the possibility of pouchitis occurring and the likely functional outcome. A pouch support nurse, stomatherapist and patient support group can offer valuable advice but in the end the patient must decide.

The indications include:

- ulcerative colitis
- familial adenomatous polyposis (FAP)
- non-acute severe colitis; any severely ill patient should have an initial colectomy
- absence of low rectal cancer; where a cancer is present, it must be possible to achieve locoregional clearance, an assessment similar to that made when considering neoadjuvant chemoradiotherapy or anterior resection or total rectal excision for 'ordinary' rectal carcinoma. The operation is not indicated in patients with disseminated disease
- adequate anal sphincter; manometry should be performed where there is clinical uncertainty of sphincter function.

Surgical controversies

Age

Failure, complication rates and function are similar in paediatric patients to overall series. General health and quality of life is similar to that of healthy children in those patients with a functioning pouch. There is some evidence that incontinence, usually minor, is more common in patients over 45 years. There is, however, no absolute contraindication in older patients and the decision should depend on assessment of the individual patient, particularly regarding sphincter function.

Female fertility

Female infertility is increased by two to three times following restorative proctocolectomy. This applies to both ulcerative colitis and FAP but more so in the former. There is also a higher incidence of fertility treatment among patients after restorative proctocolectomy than in the normal population. Fertility is not affected by colectomy. The pelvic dissection is one factor responsible as well as the advancing age of the patient. Fertility is of medicolegal importance when counselling females of child-bearing age. The patient may decide to have a restorative proctocolectomy accepting the risk of reduced fertility or she may decide to have a colectomy with ileostomy allowing recovery from the disease while preserving fertility. A restorative proctectomy can then be considered at a later date convenient to the patient.

Crohn's disease

With the exception of one group, patients with Crohn's disease experience a higher failure rate than the general pouch population. In one series failure rates for ulcerative colitis and Crohn's disease were 10% and 50%, respectively. Over a 20-year period of follow-up failure occurred in 55%. Failure in Crohn's disease is significantly greater than in indeterminate colitis.

Table 30.9 Outcome of restorative proctocolectomy in Crohn's disease

Study	N	Failed (%)
Galandiuk SS *et al.* (1990)	16	4
Deutsch AA *et al.* (1991)	9	4
Hyman NH *et al.* (1991)	25	7
Grobler SP *et al.* (1993)	20	8
Panis Y *et al.* (1996)	31	2
Regimbeau *et al.* (2001)	41	3
Tulchinsky H *et al.* (2003)	13	6
Hahnloser DPJ *et al.* (2007)	44	20

Thus, as a general principle, Crohn's disease is a contraindication to restorative proctocolectomy (Table 30.9).

Indeterminate colitis

Indeterminate colitis without radiological or clinical evidence of Crohn's disease tends to behave like ulcerative colitis. Failure rates in large series followed for 10 or more years are around 10% and at 20 years there was no significant difference in the failure rates among patients with ulcerative or indeterminate colitis (6% and 12%). Complications and function also appear to be similar to patients having the operation for ulcerative colitis. Exclusion of small bowel and anal disease is obligatory.

Previous anal pathology

A history of anal disease may suggest Crohn's disease. The presence of an anal lesion increases the risk of anastomotic leakage, pouch – vaginal and perineal fistula and subsequent failure.

Sclerosing cholangitis

Patients with sclerosing cholangitis have double the incidence of pouchitis after restorative proctocolectomy. They are also at increased risk of dysplasia developing in the pouch, although this is small. While not a contraindication, the patient should be carefully counselled. Liver function tests should be performed routinely preoperatively.

Operative steps

The steps in the operation include:

1. mobilization of the colon and rectum: this is identical to conventional proctocolectomy
2. division of the gut tube
3. the rectum is mobilized to the anorectal junction. If a stapled ileoanal anastomosis is intended, a transverse stapler is applied at this level. Where a manual anastomosis is to be carried out, the bowel is divided, leaving an open anal stump
4. mobilization of the mesentery
5. having removed the surgical specimen, the small bowel mesentery is fully mobilized. It is useful to perform a trial descent to the anal canal of the point on the ileum selected for the ileoanal anastomosis. If further mobilization is necessary, this may require the division of selected vessels but care must be taken to avoid ischaemia
6. ileal reservoir formation
7. anastomosis
8. defunctioning ileostomy.

The two-loop (J) reservoir is easy to make by hand or by stapling. The original three – loop (S) reservoir of Parks often led to evacuation difficulty due to the short segment of ileum distal to the pouch. The four-loop (W) reservoir achieves a capacitance generally greater than that of the J reservoir and similarly has no distal segment (Figure 30.40). In general, the larger the reservoir, the lower the stool frequency. An operative image of the J reservoir is shown in Figure 30.41.

Anastomosis

Manual

A mucosectomy is performed via an endoanal approach. Using suitable retraction (e.g. the Lone Star) the mucosa is removed by sharp scissor dissection after elevation by the submucosal injection of saline with adrenaline (1/300 000). The reservoir is then brought through the anal canal and sutures (12 sutures, one for each hour of the clock) are placed after removal of the retractor to minimize tension.

Stapled

A transverse stapler is applied at the level of the anorectal junction and the bowel is then divided. The anvil of a circular stapling instrument is fixed in the reservoir by a pursestring suture and the anastomosis completed on firing the instrument after insertion *per anum*.

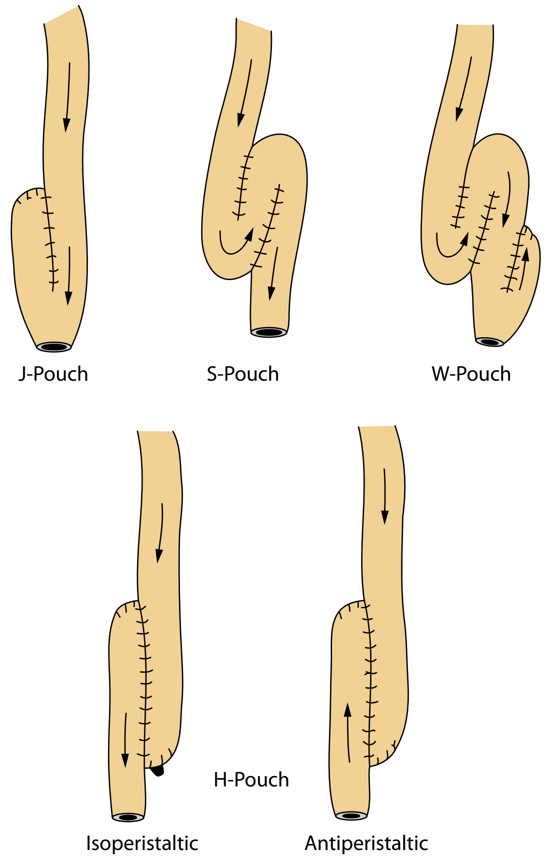

Figure 30.40 Diagrammatic representation of the various forms of pouches used after colectomy and mucosal proctectomy. The J pouch is the most extensively used since it is the simplest to create, is attended with the lowest incidence of complications and functions best in the long term.

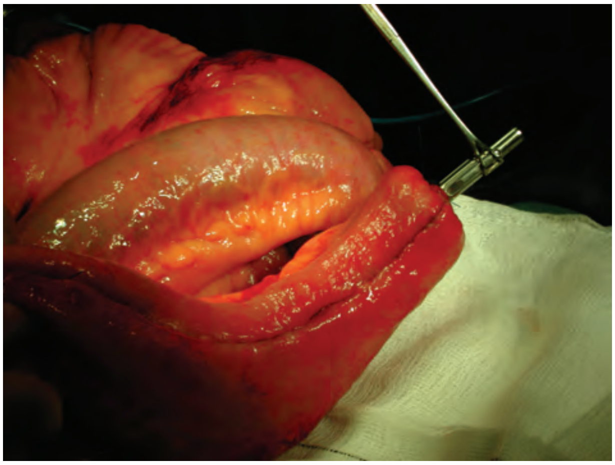

Figure 30.41 Pouch anastomosis using the J-pouch configuration

The manual technique allows a precise level for the anastomosis and avoids the possibility of leaving rectal mucosa behind, while stapling may sometimes result in an anastomosis to the rectum leaving a length of distal proctitis. This may cause continuing bleeding, discomfort, urgency and evacuation difficulty. 'Strip proctitis' or 'cuffitis' has been reported in around 10–15% of cases having a stapled anastomosis with a small cumulative risk of dysplasia of 3% over a mean follow-up of 16 months in one study. A few cases of carcinoma distal to the ileoanal anastomosis have been reported but these have occurred in patients who had either dysplasia or invasive cancer in the original operative specimen.

A stapled anastomosis is easier and quicker to perform and it may cause less trauma to the anal sphincter and is preferred for patients in whom there may be tension in the mesentery on bringing the reservoir down to the anal level. A recent meta-analysis of 21 comparative studies has demonstrated no significant differences in the incidence of postoperative complications between the two types of anastomosis. The incidence of nocturnal seepage and pad usage favoured the stapled anastomosis but persisting symptoms due to inflammation or dysplasia favoured the manual technique. The surgeon should be capable of using either method (Figure 30.42).

Most surgeons include a defunctioning ileostomy routinely. The ileostomy can cause morbidity, however, in both its formation and its closure and this may account for 20% of complications. The operation has been carried out without ileostomy with excellent results. However, in a meta-analysis the rate of anastomotic leakage and the subsequent development of an anal lesion was double in patients not given a defunctioning ileostomy.

Postoperative outcomes

Failure is defined as the need for excision of the reservoir or indefinite diversion. The learning curve in ileal pouch surgery is related to failure which improved following an initial training period of 23 cases in one study. Adequate results for manual anastomosis followed an initial period of 31 procedures.

Reports on failure in the early years after closure of the ileostomy gave rates ranging from around 5% to 10%. Over the longer term failure continues in a linear manner with rates approaching 15% at 15 years although in another large study a failure rate of 3.7% at 5 years had risen to only 7.9% at 20 years (Table 30.10).

The reasons for failure include pelvic sepsis (50%), poor function (30%) and pouchitis (10%). Pelvic sepsis in the early postoperative period confers a fivefold increase in the chance of subsequent failure. In a series of 1965 patients treated in a single centre between 1983 and 2001, four preoperative and four postoperative factors were found to be associated with ileal pouch failure. Using a multifactorial survival analysis, each

† Patients with ulcerative colitis only.

factor was assigned appropriate weights to form a scoring system for quantifying the risk of pouch failure in individual patients (Table 30.11).

Complications

Morbidity ranges from 20% to 50%. Many complications resolve spontaneously but some may require active intervention.

Pelvic sepsis

Pelvic sepsis owing to breakdown of the ileoanal anastomosis or an infected haematoma, or both has been reported in 5–20% of patients. A pyrexia develops within a few days and digital examination *per rectum* may reveal an anastomotic defect or an extraluminal swelling (usually posterior) indicating the presence of a collection. The passage of fresh blood is highly suggestive of sepsis. A CT scan and examination under anaesthesia should be performed and any collection drained into the lumen.

Stricture

Stricture of the anastomosis requiring active intervention (either dilatation or a more major procedure) has been reported in 15% to over 30%.

Intestinal obstruction

This occurs in 5–20% of patients and surgery may be necessary, although most cases resolve spontaneously.

Pouch–vaginal fistula

Pouch–vaginal fistula (the male equivalent is pouch–perineal fistula) occurs in 5–10% of (female) patients and is an important reason for late failure. It can occur months or years after closure of the ileostomy and is associated with an anastomotic complication in most cases. Patients with indeterminate colitis or Crohn's disease have a significantly higher incidence ulcerative colitis patients (hazard ratio 1.4, 2.2 respectively). The presence of perianal abscess or fistula *in ano* preoperatively is associated with 3.7- and sixfold increases in the risk of developing pouch–vaginal fistula.

Function

Frequency ranges from a median of four to seven defecations per 24 hours, but 20–30% of patients have a frequency of eight or more. This is usually regarded by the patient as acceptable, probably because urgency is present in less than 5% of patients. Nocturnal defecation is probably the most sensitive indicator of function. Frequency varies spontaneously and is also influenced by diet. Continence rates also vary, but faecal incontinence is rare (5%). The need for antidiarrhoeal medication ranges from 20% to 50%.

(a) From Fazio *et al.* *Ann Surg* 2003; **238**:605–14, with permission.

There is a tendency for function to improve with time with regards to bowel frequency; however, seepage and minor incontinence tend to worsen with time. Based on the results of the Association of Coloproctology of Great Britain and Ireland (ACPGBI) Ileal Pouch registry of over 2500 pouch surgeries, the long-term frequency of defecation remained stable at a median of around six times per 24 hours and one per night when followed over 20 years. Minor incontinence (seepage) has increased from 4% to nearly 20% during the same period. Similar results for minor incontinence (3.9% at 1 year, 21% at 20 years) with a sight increase in 24 hour frequency (7.2 at 1 year, 8.4 at 20 years) have been reported by others. Function is therefore well maintained over time with a small decline in continence. See Table 30.12 for the long-term functional outcomes following restorative proctocolectomy based on the data from the ACPGBI Ileal Pouch Registry.

Long-term outcomes

General

Deficiencies of iron and vitamin B_{12} occur in less than 10% over a follow-up of 2–3 years. These may be associated with anaemia. There is a rise in the concentration of bacteria in the pouch by over a million-fold from the concentration of 10^4–10^6 colony-forming units per gram of faeces found in the normal terminal ileum.

Pouchitis

The small bowel mucosa develops a degree of villous atrophy in almost all cases (including those with FAP). The endoscopic appearances of a non-inflamed pouch are shown in Figure 30.43. In some patients, however, acute inflammation occurs and when this is associated with frequency, urgency, liquid stool and extra-alimentary manifestations the condition is known as pouchitis (Figure 30.43). There is evidence that pouchitis occurs early after closure of the ileostomy. It is rare in FAP and is more common in non-smokers and in patients with sclerosing cholangitis.

The cumulative incidence over 5 years approaches 50% but the prevalence of unremitting chronic pouchitis is only about 5%. The diagnosis depends on clinical, endoscopic and histopathological features, the last being essential and must show acute inflammation. Grading systems to assess severity have been described. A bacterial cause is likely to be partly responsible since pouchitis responds to antibacterials and probiotics. Antibacterial drugs, including metronidazole, ciprofloxacin and augmentin, can induce a response in over 80% of patients. Maintenance of remission by daily administration of the probiotic VSL3 has been shown to be effective in 85% of patients compared with controls (0%) when taken over a 9 month period. Withdrawal of treatment is followed by recurrence. Long-term metronidazole should be avoided due to the risk of peripheral neuropathy. An algorithm for the treatment of pouchitis is shown in Figure 30.44.

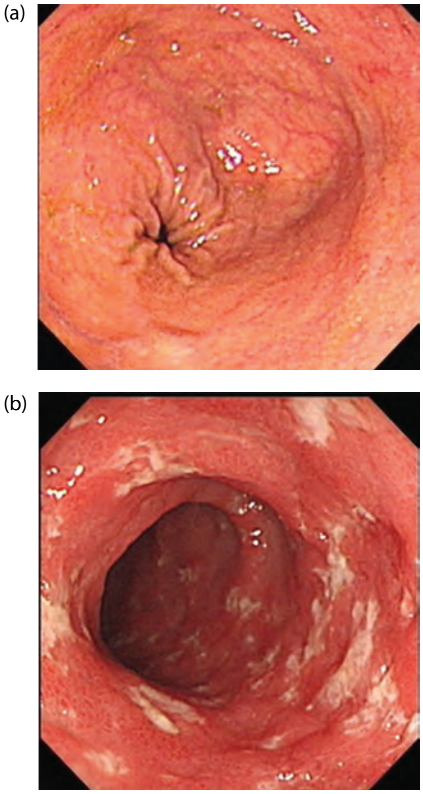

Figure 30.43 Normal pouch appearances (a) and pouchitis on endoscopy (b).

Table 30.12 Long-term functional outcomes of pouch formation

Functional outcome	1 year	5 years	10 years	15 years	20 years
Median stool frequency					
Per 24 hours	5	5	6	5	5
Night	0	0	1	0	1
Seepage – daytime	3.9%	3.8%	6.6%	7.2%	20.5%
Seepage – night	8.0%	8.2%	10.6%	10.1%	15.4%
Pad use – daytime	2.9%	2.5%	5.9%	5.8%	12.8%
Pad use - night	6.1%	5.0%	7.2%	8.7%	17.9%
Faecal urgency	5.1%	5.9%	9.4%	9.1%	2.9%
Antidiarrhoeal medication	38.9%	34.0%	37.2%	25.4%	38.5%

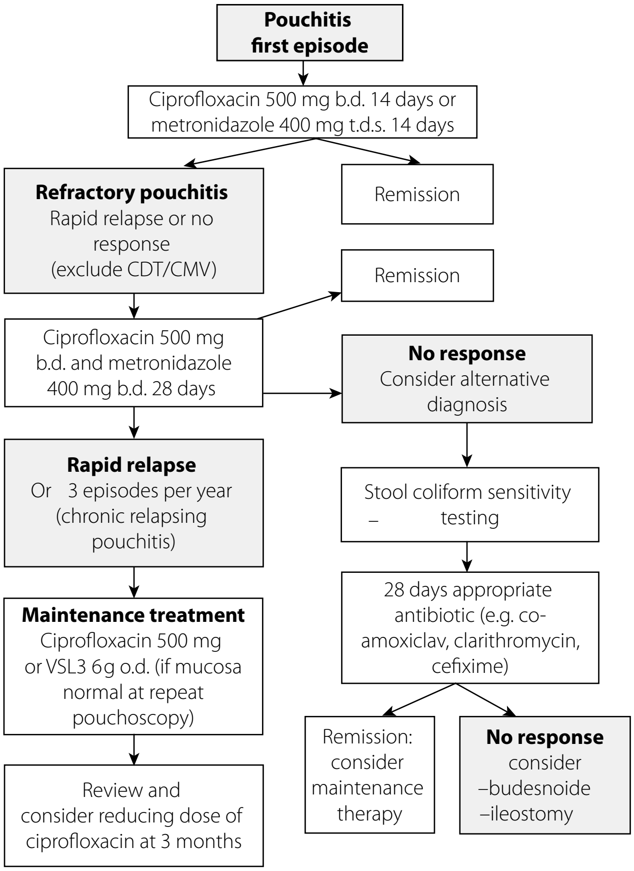
Removal of the reservoir for pouchitis accounts for only 10% of failures. Defunctioning does not affect the degree of inflammation, and excision with construction of a new reservoir is followed by pouchitis.

Neoplastic transformation

Dysplasia in the pouch mucosa is rare. To date over 20 case reports of carcinoma in the pouch or the distal anorectal segment have been described. Almost all of these had either dysplasia or a carcinoma in the original operative specimen and in none did the carcinoma appear within less than 10 years from the diagnosis of ulcerative colitis. These patients should be selected for surveillance by endoscopy with multiple biopsies at yearly intervals beyond 10 years from the onset of colitis. A suggested surveillance protocol is shown in Figure 30.45.

Salvage surgery

Removal of the pouch has a significant morbidity, with readmissions and delayed healing of the perineal wound in 40%



Pouchitis first episode
Ciprofloxacin 500 mg b.d. 14 days or metronidazole 400 mg t.d.s. 14 days
Refractory pouchitis
Rapid relapse or no response (exclude CDT/CMV)
Remission
Remission
Ciprofloxacin 500 mg b.d. and metronidazole 400 mg b.d. 28 days
No response
Consider alternative diagnosis
Rapid relapse
Or 3 episodes per year (chronic relapsing pouchitis)
Stool coliform sensitivity – testing
Maintenance treatment
Ciprofloxacin 500 mg or VSL3 6g o.d. (if mucosa normal at repeat pouchoscopy)
28 days appropriate antibiotic (e.g. co-amoxiclav, clarithromycin, cefixime)
Review and consider reducing dose of ciprofloxacin at 3 months
Remission: consider maintenance therapy
No response
consider –budesnoide –ileostomy

of patients. Thus, where failure is threatened by sepsis or poor function, it may be in the patient's interest to consider a salvage procedure which may be less traumatic and offers a chance of retaining satisfactory anal function.

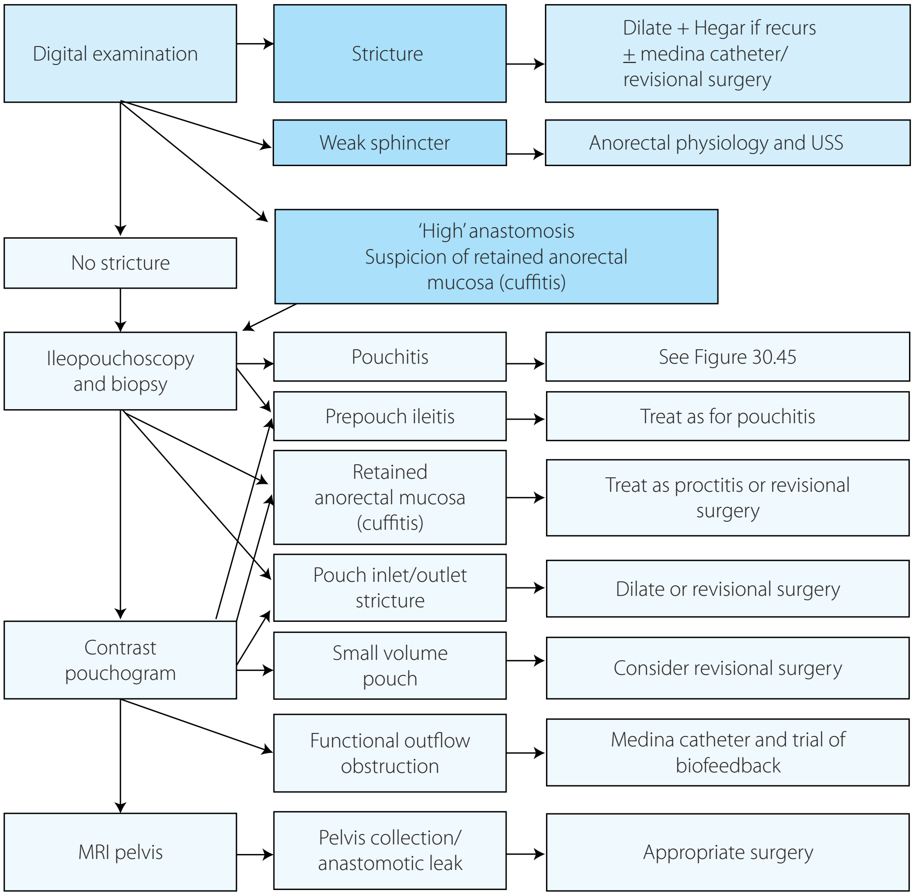
Such patients often have poor function and should be investigated by contrast radiology, including evacuation pouchography, anal manometry, pouch volumetry, MRI and histopathological examination of biopsy material. Action will depend on the diagnosis (Figure 30.46).

Success rates for abdominal salvage for pelvic sepsis range from <30% to 80%. Pouch–vaginal fistula should be treated by defunctioning followed by an attempt at repair. If low a local approach via the endoanal or transvaginal route will be necessary and success rates of around 60% of patients have been reported, although late recurrence can occur. If high (usually associated with a stapled ileoanal anastomosis), abdominal advancement of the anastomosis with mucosectomy has achieved success in over 70%. Pouch–perineal fistula in males is difficult to close but management by a long-term seton can be satisfactory.

Abdominal revision for mechanical outflow obstruction due to anastomotic stricture or a retained rectal stump is successful in 70–90%. This is significantly higher than the rates achieved when sepsis is the indication for salvage (Figure 30.47). Augmentation of a small volume reservoir may improve function.

The key points in the management of ulcerative colitis are listed below.

- The prevalence of ulcerative colitis is about 160 per 100 000 population compared with about 50 per 100 000 for Crohn's disease.
- At presentation, 50% of cases have disease confined to the rectum; in 30% this extends to the left colon, and in a further 20% disease extends beyond the splenic flexure.
- About 25% of patients with ulcerative colitis will develop at least one extra-alimentary manifestation during the course of the illness such as arthropathy, primary sclerosing cholangitis, erythema nodosum or uveitis.
- The incidence of cancer in patients is estimated to be <1% within 10 years of onset of ulcerative colitis, 10–15% in the second decade and over 20% in the third.
- Histopathological examination of a mucosal biopsy is the basis for the diagnosis of ulcerative colitis.
- The initial treatment of acute severe colitis is medical but about 30% of patients will require surgery. Surgery is absolutely indicated in cases with acute toxic dilatation or perforation.
- The operation of choice for acute severe colitis is subtotal colectomy with ileostomy and preservation of the rectal stump.
- Indications for elective surgery for chronic ulcerative colitis include failure of medical treatment, growth retardation in the young and neoplastic transformation.
- Restorative proctocolectomy is the procedure of choice for the majority of patients with chronic ulcerative colitis.



Digital examination
Stricture
Dilate + Hegar if recurs ± medina catheter/ revisional surgery
Weak sphincter
Anorectal physiology and USS
No stricture
'High' anastomosis Suspicion of retained anorectal mucosa (cuffitis)
Ileopouchoscopy and biopsy
Pouchitis
See Figure 30.45
Prepouch ileitis
Treat as for pouchitis
Retained anorectal mucosa (cuffitis)
Treat as proctitis or revisional surgery
Pouch inlet/outlet stricture
Dilate or revisional surgery
Contrast pouchogram
Small volume pouch

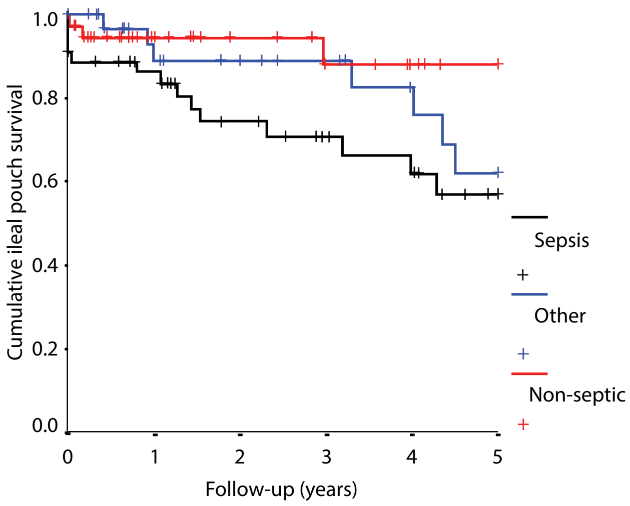

Figure 30.47 Anal function up to 5 years following abdominal salvage surgery for septic and non-septic indications

- Contraindications to restorative proctocolectomy include Crohn's disease, indeterminate colitis favouring Crohn's disease, weak sphincter and patient choice.
- The choice of ileal pouch reservoir (J vs W) or type of anastomosis (hand - sewn vs stapled) has similar postoperative outcomes and bowel function.
- One-third of patients undergoing restorative proctocolectomy (RPC) develop at least one adverse event, which include anastomotic separation, pelvic sepsis, anastomotic stricture, fistula, small bowel obstruction, bleeding or pouchitis.
- Ileal pouch failure is a time-dependent outcome with an estimated 5–10% pouch excision rate or indefinite diversion at 10 years following RPC.
- In patients who are threatened with pouch failure salvage surgery may be considered, with successful outcome in 75% of patients.

Radiation proctitis

The pathology of this condition is covered by the section on radiation enteropathy in the small bowel chapter. Clearly, radiation proctitis only occurs when the intact rectum is irradiated in the course of pelvic radiotherapy. This is usually delivered for the treatment of cervical, bladder or prostatic cancer. However, with increasing interest in the local treatment of rectal cancer, radiation proctitis can be a problem, especially when local excision is combined with external beam therapy. In addition, if pre- or postoperative radiotherapy is employed with anterior resection, the rectal remnant or (in the case of postoperative treatment) the colon used in the reconstruction can be affected. The main symptoms are rectal bleeding and diarrhoea, but in severe cases stricturing or fistulation into the vagina or bladder may occur. In extreme situations, a diversion colostomy or even rectal excision may be required.

Diversion colitis

When a section of the large bowel is isolated from the rest of the colon (usually the rectum and distal sigmoid after a Hartmann's procedure) the mucosa may become inflamed, causing mucus discharge, rectal bleeding and tenesmus. Histologically, this is indistinguishable from ulcerative colitis, but is thought to be due to a lack of intraluminal short-chain fatty acids. There is some evidence that the condition responds to butyrate-containing enemas.

Neutropenic colitis

This may occur as a complication of chemotherapy (especially for leukaemia or lymphoma), but it may also occur in other neutropenic patients and it has been reported in patients with large bowel and terminal ileal carcinoma. It is caused by superinfection by *C. septicum* or other clostridial species (*Clostridium sphenoides, C. perfringens, C. sordellii,* etc.), with the development of gas gangrene of the bowel and severe toxaemia. Fulminating neutropenic colitis carries a mortality of close to 100% as the only effective treatment is colectomy, and this is usually contraindicated by the underlying condition.

Collagenous colitis

Histologically, this disease is characterized by debasement of the epithelium, loss of goblet cells, neutrophil infiltration and subepithelial deposition of collagen which forms an irregular layer 7–25 mm in thickness. Its aetiology is unknown, and it presents with diarrhoea. The symptoms may respond to sulfasalazine, but in severe cases steroid therapy is required.

Infections and infestations of the large bowel

Amoebic dysentery

Amoebic dysentery is caused by *Entamoeba histolytica* which exists either as an active motile trophozoite or as a cyst. The former is characteristic of amoebic dysentery whereas the latter is more hardy and occurs in formed stool. The cysts are responsible for transmission of the infection. Amoebiasis is a common cause of diarrhoea in warm and humid parts of the world but sporadic cases may also occur in Europe and the USA. The amoebae cause colonic ulceration with the intervening mucosa being normal or hyperaemic.

Clinically the symptoms may be similar to ulcerative colitis and vary from mild diarrhoea to severe bloody diarrhoea. Metastatic amoebic infection may occur throughout the body with liver abscesses being the most common. These occur in 1–3% of cases and present with fever, pain and tenderness in the right upper quadrant. Alternatively they may present with a pyrexia of unknown origin. Amoebic dysentery may also be complicated by colonic perforation, stricture formation or severe haemorrhage.

Definitive diagnosis is made by stool microscopy, rectal biopsy or serology. The stool is examined for trophozoites and cysts but the former are difficult to find unless fresh specimens are examined. Rectal biopsy is useful as amoebae may be seen in the surface exudate or within the lymphatics. Serology is most valuable in patients who have amoebiasis outside the intestine when the stool tests are often negative. Serology is also useful for patients with suspected IBD in order to exclude amoebiasis. The drug of choice is metronidazole for acute amoebic dysentery whereas diloxanide furoate is effective in chronic intestinal infections associated with cysts in the stool.

Bacillary dysentery

This is due to infection with *Shigella* organisms and four main serologically distinct groups are implicated in human disease: *Shigella dysenteriae, S. flexneri, S. boydii* and *S. sonnei*. The disease is spread by person-to-person contact, as faecal excretion of the bacterium continues for 1–4 weeks in untreated individuals. The organism invades the colonic wall leading to ulceration and the clinical features are characterized by fever, abdominal pain and watery diarrhoea leading to passage of blood and mucus. Complications include haemolytic uraemic syndrome, aseptic meningitis and Reiter syndrome (arthritis, uveitis and conjunctivitis). This last complication is associated with HLA-B27. The diagnosis is made by stool culture and serotyping for identification of the specific species. The disease is self-limiting and is usually quite mild but in severe cases ampicillin or co-trimoxazole should be used. It may also be necessary to apply specific rehydration therapy, preferably orally although intravenous fluids are sometimes required.

Salmonellosis

Salmonella may cause simple gastroenteritis, which is common in the developed world, or typhoid, which is common in areas with poor sanitation. *Salmonella* gastroenteritis is caused by *Salmonella typhimurium* and *S. enteritidis* and the major non-human reservoir of these organisms is in poultry and domestic livestock. Typhoid on the other hand is caused by *S. typhi* and *S. paratyphi* and humans are the only important reservoir for these organisms. *Salmonella* infections involve both the small intestine and the large intestine. The three major patterns of *Salmonella* infection are:

- acute gastroenteritis
- typhoid (enteric) fever
- asymptomatic carrier state.

Salmonella gastroenteritis

This is relatively common with about 500 cases per 1 000 000 of the population occurring each year in the UK. The symptoms of gastroenteritis including headache, abdominal pain, fever and diarrhoea develop between 8 and 48 hours after eating contaminated food. The stool is watery and very rarely contains blood. The diagnosis can be made by culture of the stool. The disease is self-limiting and antibiotics are not valuable unless the patient is very ill with bacteraemia. In severe cases patients may require to be hospitalized and resuscitated with intravenous fluids.

Typhoid fever

Here the incubation period is in the region of 10–20 days and the clinical onset consists of progressive fever, vague abdominal pain, headache and cough. After about 5 days the patient develops abdominal distension, diarrhoea and splenomegaly. A cutaneous vasculitis occurs mainly on the abdomen giving rise to characteristic 'rose' spots. The disease may be complicated by intestinal haemorrhage and perforation and systemic problems including meningitis, encephalomyelitis, disseminated intravascular coagulation, hepatitis, pancreatitis and ectopic *Salmonella* infections (e.g. in bone).

Diagnosis is made by culture of the organism from blood, stool, urine or bone marrow. Blood cultures are positive in 80% of patients in the first week of symptoms, whereas the stool cultures are usually positive during the second and third weeks. Serological tests can be useful when culture facilities are not available and a rising titre of O antibody indicates active infection. Typhoid fever should be treated with antibiotics and the most effective drug is chloramphenicol. However, drug-resistant organisms are becoming common and it may be necessary to use amoxicillin or co-trimoxazole. When perforation occurs laparotomy with peritoneal cleansing and simple closure of the perforation is necessary. This must be supplemented with antibiotic therapy (see also Chapter 29).

Asymptomatic carriers

Carriers of *S. typhi* are important to identify as they represent a major source of the disease. The bacterium is commonly carried in the gallbladder and cholecystectomy may be necessary. Recently, however, ciprofloxacin, with its good biliary penetration, has been shown to be reasonably effective in eliminating the carrier state.

Escherichia coli infections

E. coli is a normal commensal of the gastrointestinal tract of human beings and most strains are harmless. Some strains however cause gastroenteritis. These are divided into four main groups:

- enteropathogenic
- enterotoxigenic
- enteroinvasive
- enterohaemorrhagic.

Pathogenic strains of *E. coli* can be spread by the ingestion of contaminated food (often cold meat) and by person-to-person transmission. Often both types of spread can be implicated in an epidemic with contaminated food being the initiating factor and a second wave of infection being caused by person-to-person transmission. The most common pathogenic serotype is 0157:H7, which produces cytotoxins and may lead to the haemolytic uraemic syndrome. This carries a high mortality, particularly in elderly individuals. Diagnosis of *E. coli* infection is made by the isolation of the pathogenic strain from the stool but tests for verotoxin can be more sensitive than culture.

Campylobacter infection

In man, *Campylobacter* infections are usually the result of ingestion of infected food, and poultry in particular. However, they may also be water borne, milk related and contracted from dogs. *Campylobacter* species affect both the small and large intestine and most strains produce an enterotoxin and one or more cytotoxins. Clinically there is usually a self-limiting episode of diarrhoea which lasts for a few days, and this may be preceded by fever, headache, myalgic malaise and abdominal pain. Rectal bleeding often follows the diarrhoea. Diagnosis is made by stool culture and the bacterium may be present in the stool for up to 5 weeks. Occasionally, infection may be complicated by massive lower gastrointestinal haemorrhage, Reiter syndrome and Guillain–Barré syndrome. As the majority of infections are self-limiting, treatment is not usually necessary but, in a prolonged illness, antibiotics such as erythromycin, tetracycline, chloramphenicol and gentamicin are appropriate.

Clostridium difficile infection

C. difficile is a large Gram-positive anaerobic bacillus which produces two toxins, A and B. A is directly cytotoxic to colonic epithelial cells but the role of B is not completely clear. *C. difficile* infection (CDI) is important in both antibiotic-associated diarrhoea and the more serious pseudomembranous colitis. There has been a significant increase in CDI in most Western countries and large outbreaks of CDI-associated colitis have been caused by the PCR ribotype O27 CD strain (CD027). Epidemiological studies have indicated that CD027 is most frequently acquired in the community and emerges sporadically in hospital patients following administration of antibiotics.

Pseudomembranous colitis is a form of colitis in which a pseudomembrane is caused by surface inflammatory exudate. Both mild CDI and pseudomembranous colitis are associated with the use of almost all antibiotics, although lincomycin, clindamycin, ampicillin and amoxicillin account for about 80% of all cases. The pathogenesis of both forms of CDI is unclear. The organism is present under normal circumstances in the stools of about 2% of the population but it may be present in small numbers in a much larger proportion. The factors which favour proliferation of *C. difficile* in the colon are unclear but the administration of antibiotics is clearly of major importance. General practitioners and hospital doctors are now under strict guidelines to avoid prescription of unnecessary antibiotics and hospitals have antibiotic policies which indicate the antibiotics which can be used in patients that need this treatment.

Strict personal hygiene, such as washing hands after going to the toilet, can reduce the spread of these infections. Good cleaning practices and strict hygiene measures in hospitals help to prevent contamination of equipment and personnel with bacteria and spores as *C. difficile* is very contagious and it can spread very easily through fomites. Other suggested contributory factors include proton pump inhibitor administration.

Clinically, the disease varies from a mild illness with a moderate increase in bowel frequency to severe bloody diarrhoea associated with marked abdominal pain and tenesmus. Fever is present in the majority of cases, and on examination there may be abdominal tenderness and peritonism. While the disease usually begins during a course of antibiotics, in about 30% of cases symptoms may start after the antibiotic has been discontinued. CDI may occur and complicate patients suffering from ulcerative colitis.

Diagnosis

The diagnosis is made by both culture of *C. difficile* from stool and from the demonstration of the toxin (usually B) in the stool. Most laboratories perform toxin tests based on an enzyme immunoassay (EIA) method. These tests have sensitivities ranging from 60% to 70% and specificities of 98%. Symptomatic patients with negative tests should be tested by other more sensitive tests: cell culture cytotoxicity neutralization assays (CCNAs). Toxigenic culture has emerged as the new gold standard but because these assays detect a gene that encodes toxin and not the toxin itself, it is important that these tests are performed only in patients with diarrhoea. These more recent molecular assays have been shown to be superior to toxin EIAs and CCNA but not to toxigenic culture.

The diagnosis of pseudomembranous colitis depends on endoscopic appearances which consist of exudative punctate raised plaques with intervening areas of oedematous mucosa. Biopsy shows areas of focal necrosis with polymorphonuclear leucocytes forming characteristic 'summit' lesions.

Treatment

Mild disease

The first measure in the treatment of patients with CDI is to discontinue the antibiotic responsible for the disease to enable the normal colonic flora to recover. This measure alone has been shown to be effective in 15–25% of patients. Fluid and electrolyte replacement may be necessary in these patients. Patients with mild CDI (diarrhoea with minimal symptoms) are monitored for 48 hours for symptomatic improvement before treatment with an antibiotic is instituted. Patients with more serious infection (high fever, pronounced leucocytosis, severe abdominal pain and absence of diarrhoea) require early institution of the appropriate antibiotic therapy.

Antibiotic therapy

Vancomycin and metronidazole are the two primary antibiotics used in the treatment of CDI in 7–10 day courses. Oral metronidazole is the preferred therapy as it is readily absorbed in the upper gastrointestinal tract, and usually well tolerated (250–500 mg administered four times daily or 500–750 mg three times daily). In patients who are intolerant to oral metronidazole, the antibiotic is administered intravenously (500–750 mg three or four times a day). Side effects of metronidazole include an unpleasant metallic taste, nausea, vomiting, diarrhoea, abdominal pain, headache, pruritus, erythematous rashes, dizziness and reversible neutropenia. Vancomycin is usually reserved for severe, life-threatening CDI, for patients unable to tolerate metronidazole or for patients without symptom resolution after completing a course of metronidazole. The recent emergence of vancomycin-resistant organisms is a growing concern. Oral vancomycin, which is not appreciably absorbed and is excreted in the stool unchanged, administered in oral doses of either 125 mg or 500 mg four times daily in adults are recommended. The use of a rectal vancomycin enema (500 mg diluted in 1000 mL of 0.9% sodium chloride injection) is an alternative. Several randomized clinical studies have not shown significant differences between the results of metronidazole and vancomycin therapy in the treatment of CDI. In a recent Cochrane review, Nelson concluded that one should choose the antibiotic that brings both symptomatic cure and bacteriological cure. In this regard, teicoplanin appears to be the best choice because the available evidence suggests that it is better than vancomycin for bacteriological cure and has borderline superior effectiveness in terms of symptomatic cure. However, this antibiotic therapy is currently not available in the USA.

Approximately 20–50% of patients have a relapse of diarrhoea from CDI after an initial course of antibiotic therapy. Recurrent episodes respond to the same 10 day course of antibiotic therapy used in the first episode.

Alternative therapies

Alternative antibiotics for CDI include bacitracin and teicoplanin. Binding resins such as cholestyramine or colestipol are less effective.

Faecal microbiota transplantation (FMT)

FMT (previously known as faecal bacteriotherapy) is increasingly used in the treatment of recurrent disease. Faecal transplantation is performed at colonoscopy by infusing fresh donor faeces into caecum. The patients have a whole-bowel lavage with polyethylene glycol solution prior to FMT. FMT has also been reported to benefit other colonic disorders, e.g. constipation and IBS. Intravenous immunoglobulin is used in some centres for severe disease but evidence for the efficacy of this treatment remains uncertain.

Severe disease

There is no consensus definition for severe CDI, nor is there agreement on the most important clinical indicators that differentiate disease severity. Thus various systems are used.

- Traditional indices of severe CDI: white blood cell (WBC) count >15 000 cells/μL or a serum creatinine level ≥1.5 times the premorbid level.
- Indices based on the Quebec outbreak: WBC count >20 000 cells/μL and elevated serum creatinine – significantly elevated WBC counts in the absence of any other cause should raise suspicion for CDI.
- Scoring system used in clinical trials to identify patients with severe infection – one point each is given for age >60 years, temperature >38.3°C, serum albumin <2.5 mg/dL (25 g/L), or peripheral white blood cell count >15 000 cells/μL within 48 hours of enrolment to study. Two points are given for endoscopic evidence of pseudomembranous colitis or treatment in the intensive care unit. Patients with two or more points are considered to have severe disease.
- Severe disease defined as ≥10 bowel movements per day, a peripheral WBC count ≥20 000 cells/μL or severe abdominal pain.

The reported incidence of severe CDI varies widely given the lack of a consensus definition. The risk of complications during first CDI recurrence in the Quebec outbreak caused by the hypervirulent North American Pulsed Field type 1 (NAP1) strain was 11%. Complications included shock, need for colectomy, megacolon, perforation or death within 30 days. Older age, high leucocyte count and acute renal failure were strongly associated with a complicated course.

Treatment

Patients with severe CDI should receive antibiotic therapy, supportive care and close monitoring in ICU. Surgery should be considered if the patient's clinical status fails to improve and the serum lactate rises above 2.2. Toxic megacolon should be suspected if the patient develops abdominal distension with diminution of diarrhoea (reflects onset of paralytic ileus resulting from loss of colonic muscular tone)

Antibiotics

Oral vancomycin is the first-line therapy for severe CDI. Usually oral vancomycin is administered in doses of 125 mg four times daily in severely ill patients, as reports indicate that levels achieved with higher doses (500 mg four times daily) are equivalent. Patients with severe disease who do not demonstrate clinical improvement with oral vancomycin are changed to fidaxomicin. If this is not available, oral metronidazole (500 mg three times daily or 250 mg four times daily for 14 days) is used. In severely ill patients with paralytic ileus, intravenous metronidazole in a dose of 500 mg every 8 hours is used. Intravenous tigecycline has been used in a small number of patients with severe CDI that was refractory to standard therapy.

Intracolonic antibiotics

Vancomycin enema is an effective adjunctive therapy in patients who cannot tolerate the oral preparation, or patients who have megacolon or ileus. In a retrospective case series of nine patients with refractory symptoms, toxic megacolon or fulminant colitis, rectal vancomycin was administered in addition to standard antibiotics, eight patients had complete resolution of symptoms and one patient died from multisystem organ failure. Thus intracolonic vancomycin is particularly useful in patients with profound ileus. Although the optimal dosing and volume has not been established, rectal vancomycin is often given as a retention enema containing 500 mg in 100 mL of normal saline every 6 hours. In addition some reports suggest that patients with megacolon may benefit from colonoscopic decompression and placement of a tube in the right colon which can be perfused with a 1 mg/mL solution of vancomycin in normal saline to deliver a total dose of 1–2 g per day. According to one report, this is safely achieved by the creation of a laparoscopic terminal loop ileostomy with insertion of a Malecot catheter in the distal limb. Dose adjustments may be required depending on individual circumstances including extent of colonic disease and patient weight. The promising results with this laparoscopic approach require confirmation by larger studies. It is important to note that vancomycin can be absorbed through inflamed colonic mucosa and cause systemic toxicity.

Surgery

Emergency surgery is required for toxic megacolon, perforation or impending perforation, necrotizing colitis or rapidly progressive and/or refractory disease with systemic inflammatory response syndrome leading to multiorgan system failure. Although the optimal timing of surgery remains uncertain, the emphasis in recent years is towards earlier surgical intervention; the appropriate operation is subtotal colectomy with preservation of the rectum. In a retrospective review, colectomy was most beneficial for immunocompetent patients aged ≥65 years with a WBC count ≥20 000 cells/μL and/or a plasma lactate between 2.2 and 4.9 meq/L. The reported mortality of emergency surgery for complicated severe CDI is 40–50%.

Chlamydial infection

The commonest type of chlamydial infection is a sexually transmitted urethritis but the rectum may also be affected, particularly in men who have sex with men. This leads to an ulcerative proctitis characterized by rectal bleeding. The diagnosis depends on isolation of the organism from the rectum and treatment with tetracycline is usually effective.

Schistosomiasis

It should be remembered that the adult worms of *Schistosoma mansoni* reside mainly in the inferior mesenteric vein and *S. japonicum* in the supermesenteric vein. These worms produce large numbers of eggs, which are retained in the wall of the intestine where they cause granulomatous reactions and some penetrate the intestinal wall and are passed with the faeces. The presence of the eggs in the intestinal wall may give rise to rectal bleeding and occasionally large polypoid lesions may occur and can be misdiagnosed as cancers, usually in the descending and sigmoid colon.

Cryptosporidiosis

The parasite *Cryptosporidium* causes diarrhoea and may be fatal in immunocompromised patients, particularly those with AIDS. The parasite infects the enterocytes of both the small and large intestine and transmission appears to be either person to person or caused by ingestion of infected water. There is no known effective treatment although in normal individuals the gastroenteritis tends to be mild and self-limiting. In patients with AIDS, however, *Cryptosporidium* causes protracted watery diarrhoea with severe weight loss.

Colorectal cancer

Epidemiology

There are about 140 000 and 40 000 new cases of colorectal cancer diagnosed each year in the USA and UK respectively. Around two-thirds are located in the colon and one-third in the rectum. This equates to 55 new cases per 100 000 population in the USA and 55.9 in the UK. It is the second most common cancer in the UK (Cancer UK) and the USA (http://www.cancer.org/downloads/STT/F861708_finalforweb.pdf). The incidence of colorectal cancer is higher in males and black people. It has been also shown to increase with age, with the majority of the patients being diagnosed at the age of 50 or above. In recent years, however, there has been an increase in the number of younger patients diagnosed with the disease, raising more questions about the already established screening programmes.

Cancer of the colon and rectum is one of the few cancers that have been associated strongly with a number of environmental factors. Consequently, this has been responsible for the significant variability among different populations, and thus the higher incidence in the Western world. Furthermore, there are significant variations among subgroups of the population. In the UK, the incidence in England is significantly lower than in Scotland. The incidence in males ranges from 57 per 100 000 in England compared with 68 per 100 000 in Scotland. The pattern prevails in females (37 per 100 000 females diagnosed with colorectal cancer in England compared with 44 per 100 000 in Scotland) (Cancer UK report).

Aetiology and associated risk factors

The colorectal cancer risk is influenced by both environmental and genetic factors, with the lifetime risk up to 5%. There are a number of studies investigating the aetiology of colorectal cancer, but the exact cause is still not fully clear. There are a number of environmental and genetic factors that have been strongly associated with the disease and therefore are considered to play a role in the carcinogenesis. The exact mechanism is not fully understood yet.

Environmental factors

Diet is one of the major environmental risk factors that have been associated with colorectal cancer. It has been suggested that the Western diet is a strong risk factor (WHO Cancer report). The consumption of red meat and poultry was shown to be associated with colorectal cancer and might be a result of the exposure to carcinogens that can be created when cooking. The role of red meat was also assessed by three meta-analyses that confirmed the above statement. One study demonstrated a link to colorectal cancer when the meat was well cooked. This study suggested that carcinogens formed on the surface of well-cooked red meat might be responsible for this link, particularly for rectal cancer. Myoglobin has also been suggested to play a part in the carcinogenesis.

There are a vast number of publications debating the value and role of dietary fibre in colorectal cancer. There was initially a negative association of dietary fibre intake to colorectal cancer. The majority of the published studies showed that lower intake of vegetables and therefore fibre was associated with a lower risk of colon cancer. However, this claim was soon challenged by two meta-analyses that confirmed the benefits of a high intake of vegetables in terms of reducing the risk of colorectal cancer. Trock *et al.* demonstrated a reduction of risk by 40%, and Howe *et al.* by 50%. More recent prospective studies have been performed but did not demonstrate significant association of high-fibre intake as protective factors for cancer.

Micronutrients and vitamins have also been investigated. A study investigating the level of folate in serum showed that low serum levels were associated with higher rates of colorectal cancer. One meta-analysis showed that the risk was higher for colorectal cancer when the serum levels of vitamin D were reduced. Calcium and aspirin have been shown to reduce the risk for colorectal adenoma formation, thus reducing the risk of colorectal cancer.

Obesity is associated with a higher risk of colorectal cancer. Obesity is shown to increase the risk by around 25% in overweight males and 50% in obese males. The same study showed a non-statistically significant risk of 9% for obese females. Larger waist size was also linked to higher risk for both males and females. Physical activity has been shown to play an important role. High levels of physical activity have been shown to substantially reduce the risk, especially in males by almost 25%. Physical inactivity has been suggested to be responsible for up to 14% of the new colon cancer cases in the Western countries. The findings of the European Prospective Investigation in Cancer (EPIC) study confirmed these findings. This study also evaluated the added effect of these two factors and showed that the risk ratio of colon cancer was 0.38 in males who were both lean and active compared with patients who were inactive with a BMI >30.

Smoking and alcohol have also been investigated thoroughly and shown to increase the risk of colorectal cancer for both men and women. A meta-analysis published in 2009 demonstrated a statistically significant increase in risk of colorectal cancer (risk ratio = 1.20; $p < 0.0001$), especially in male smokers (risk ration = 1.38, $p < 0.0001$). The same study showed a dose-dependent risk. The relative risk for male heavy smokers increased to 1.28 from 1.19, which was the risk for patients who had consumed fewer than 30 pack years. Regular alcohol consumption has a dose-dependent risk of colorectal cancer. This can increase by up to 50% for an intake of 50 g/day of alcohol or above compared with occasional drinkers.

Familial and genetic factors

Family history of colorectal cancer is known to increase the risk of colorectal cancer. The risk doubles when there is a history of a first-degree family member diagnosed with colorectal cancer. The risk is even higher when the relatives were diagnosed with the disease at a younger age (younger than 50) and for patients with more than one relative with the disease.

FAP and the hereditary non-polyposis colorectal cancer (HNPCC) have been linked with about 5% of the diagnosed colorectal cancers. The presence of early multiple bowel adenomas is the distinctive feature of FAP, which is responsible for about 1% of colorectal cancers. The presence of FAP increases the risk of developing colorectal cancer to 100% by the age of 40. It is an autosomal dominant disorder, caused by a germline mutation in the adenomatous polyposis coli (*APC*) gene, which is a tumour suppressor gene and found on chromosome 5q21. Early onset of colorectal cancer is typical for HNPCC, which is estimated to be responsible for 1–4% of colon cancers. HNPCC is secondary to germline DNA mismatch repair gene mutations in the majority of the cases. The overall lifetime cancer risk of developing colorectal cancer in patients with these mutations by the age of 70 is 91% for men and 61% for women. The same study demonstrated that the risk was significantly higher for males (74%) than for females (30%; $p = 0.006$).

Other, rarer syndromes have also been shown to increase the risk of developing colorectal cancer. Peutz – Jeghers syndrome is an autosomal dominant condition characterized by the presence of hamartomatous polyps in the small bowel and mucocutaneous melanin pigmentation of the perioral region, hands and feet. Patients with the syndrome have 39% higher risk of developing colorectal cancer by the age of 70. MYH (mutY homolog gene mutation)-associated polyposis and juvenile polyposis, both autosomal dominant conditions, have been associated with 35–53% and 17–68% increased risk of colorectal cancer respectively.

Inflammatory bowel disease

Patients diagnosed with IBD carry higher risk of colorectal cancer than the general population. This risk has been extensively investigated and is well established. The risk of colorectal cancer in ulcerative colitis patients is more pronounced. Colorectal cancer on the background of chronic ulcerative colitis has been described as being more aggressive and with poorer prognosis than the general population. The prevalence of colorectal cancer in patients with ulcerative colitis has been reported up to 3.7%. The cumulative risk of developing colorectal cancer has been reported to increase by 1% per year after 10 years from the date of onset of active ulcerative colitis. The relative risk of developing colorectal cancer on the background of ulcerative colitis at an early age has been reported up to 38-fold, with reports of 14.8 and 2.8 for patients with pancolitis and left-sided colitis respectively. The risk of developing colorectal cancer in ulcerative colitis has also been found to be significantly increased in patients with total colitis.

Earlier studies showed that the incidence of colorectal cancer in patients with CD was higher cancer, with other studies showing that CD-associated colorectal cancer had a poorer prognosis than sporadic colorectal cancer. The risk ratio for developing colorectal cancer on the background of CD is 4.5 in patients with colonic disease, compared with the general population, with a cumulative risk of 2.9% at 10 years.

Clinical presentation

Initially patients with colorectal cancer may be asymptomatic. As the disease progresses, development of systemic symptoms and symptoms specific to the location of the cancer may be observed. Rectal bleeding is one of the commonest presentations of colorectal cancer. However, it may be the result of a benign pathology and therefore has low positive predictive value for colorectal cancer. The prevalence, in populations of over 20 years old, ranges between 15.5% and 24%. A recent meta-analysis of 13 studies with 18 634 patients showed a positive predictive value (PPV) of 5.3% that increased to 8.1% in a subgroup analysis of studies that included patients aged 50 or more. Heterogeneity was moderate. A study by Fine *et al.* suggested that the colour of bleeding reported by patients was inaccurate because of misinterpretation and the use of a colour card was proposed in order to help patients to be more accurate. The same study reported that the majority of bright red bleeding (about 83%) was linked to distal (60 cm) pathology. However, more proximal pathology was identified in 20 of 217 (9.22%) patients. A community-based trial showed that colorectal cancer was more likely when the blood was mixed with faeces and when it was reported as being dark (likelihood ratio 3.0). The picture is slightly different in secondary care, with the positive predictive value for colorectal cancer being higher for patients with a history of dark and bright blood (13.2%) than dark blood (10.6%) or bright blood alone (4.3%), and for when the blood was mixed with faeces (11.0%) than when separated from stools (3.4%). One study of 226 patients evaluated the risk of rectal bleeding in the presence of perianal symptoms and showed a negative likelihood ratio of 2.90, with poor sensitivity and specificity. This suggests that rectal bleeding in the presence of perianal symptoms carries low risk of colorectal cancer.

Patients with colorectal cancer often present with a ‘change in bowel habit’. The definition in the UK refers to the passage of loose stools and/or increased frequency of defecation that persists for more than 6 weeks. It has been reported by a number of studies that change in bowel habit may occur in up to 91% of patients with distal and 61% of patients with proximal cancer. Constipation is not currently considered as a risk factor; recent studies suggest that there may be a link and therefore should be used to refer patients for further investigation. A meta-analysis showed a positive likelihood ratio of 1.8 and negative likelihood ratio of 0.7 when it is associated with rectal bleeding.

Unintentional weight loss has been regarded as a predicting factor of colorectal cancer. However there has been no conclusion about the percentage of weight loss that should be considered clinically relevant. Loss of 5% of weight in a period between 6 and 12 months is generally considered significant. In colorectal cancer, weight loss is usually a late presentation with a median of 27 (9–42) weeks. The same study demonstrated a higher incidence of weight loss for proximal (46%) than distal (34%) tumours, but did not achieve statistical significance. The positive predictive value for colorectal cancer in patients with weight loss increases to 4.7% when it is associated with rectal bleeding, to 3.1% with diarrhoea and 3% with constipation. A recent meta-analysis of six studies that included 1468 patients demonstrated that the combination of weight loss and rectal bleeding increased the positive likelihood ratio to 1.88 and negative likelihood ratio to 0.93. There was low heterogeneity among the included studies.

Abdominal pain may be the first presentation. Up to 30% of the general population experience abdominal pain every year. This is usually a result of a benign condition. It has low sensitivity and specificity when it is the sole symptom. A recent meta-analysis demonstrated a positive likelihood ratio of 2.47 and negative likelihood ratio of 0.75. The same study showed low sensitivity (31%) but high specificity (91%). The heterogeneity between the studies was high though. The positive predictive value increased to 7.6% when abdominal pain was associated with rectal bleeding but the between-study heterogeneity remained high. Hamilton *et al.* demonstrated that there was an increased PPV of 3.4% when it was associated with weight loss, 3.1% with rectal bleeding and 1.9% with diarrhoea.

Iron-deficiency anaemia is present in 11–57% of colorectal cancers and is more common for right-sided tumours. The patients may present with fatigue and/or shortness of breath. In the UK, haemoglobin of <11 for females and 12 g/dL for males indicates the need for further investigations. A meta-analysis of four studies (928 patients) assessed the PPV of anaemia and found it to be high, with high heterogeneity mainly due to the significant number of true positives reported from one study. A subgroup analysis was performed excluding that study and showed a PPV of 7% with the heterogeneity between the studies reduced.

Investigation

Clinical examination

A full history and examination is essential before any management plan is made. History should also include questions assessing the patient's performance status and comorbidities, as this information may be pivotal to the management plan. During clinical examination the patient should be specifically inspected for signs of anaemia, jaundice (suggestive of liver metastases) and malaise, and examined for abdominal distension, ascites, masses and abdominal tenderness. Digital rectal examination is essential, as it can provide essential information at the initial stage if the tumour is within the lower rectum.

Blood tests

Routine blood tests are performed including a full blood count, urea and electrolytes, liver function tests and coagulation. More specifically, the haemoglobin is measured to confirm or rule out anaemia, the liver function tests and coagulation to assess the liver function and raise any question of liver metastases.

Tumour markers, such as the carcinoembryonic antigen (CEA) and cancer antigen (CA) 19-9 are measured. CEA is an oncofetal antigen discovered in 1968. It is a product of the normal fetal gut tissue and epithelial tumours, especially those of the large bowel. It can, however, increase in smokers, IBD, pancreatitis, liver disease and in patients with epithelial tumours at other sites. CA 19-9 was discovered in patients with colon and pancreatic cancer. Negative CEA and CA 19-19, with a cut-off of 5 ng/mL and 37 U/mL, respectively, have been shown to significantly improve the overall survival following potentially curative operation. Care should be taken with mucin-producing and poorly differentiated adenocarcinomas of the colon and rectum which do not often present with a raised CEA and are classed as high-risk tumours for local failure and poor long-term prognosis.

Proctoscopy and rigid sigmoidoscopy

Proctoscopy and/or rigid sigmoidoscopy can be performed in an outpatient setting, confirming a lower rectal tumour and providing at the same time the opportunity to get biopsies from the tumour and therefore plan the patient's further management more efficiently. In addition, it may reveal a different pathology (i.e. IBD) or the presence of streaks of blood in the lumen of the rectum, which is strongly indicative of pathology in the sigmoid above the reach of the rigid rectoscope.

Flexible sigmoidoscopy

Flexible sigmoidoscopy can be performed relatively quickly and is virtually risk free. Therefore, the National Institute for Health and Clinical Excellence (NICE) in the UK suggests it to be the most appropriate initial investigation for the majority of symptomatic patients, especially the patients with symptoms suggesting possible left-sided lesions. Flexible sigmoidoscope can only reach up to 60 cm. When there are no positive findings in patients without any right-sided symptoms, the likelihood of right-sided cancer is low.

Colonoscopy

NICE advises the use of colonoscopy in patients who are considered at high risk of developing colon cancer because of older age, a clinically palpable abdominal mass, iron-deficiency anaemia or symptoms such as abdominal pain with loss of appetite and weight. Colonoscopy is also necessary when there is significant clinical doubt following a flexible sigmoidoscopy. Diagnostic colonoscopy is usually appropriate for patients with right-sided symptoms, except for those with palpable masses, for whom imaging may be more appropriate (barium enema or CT). Colonoscopy should also be considered when a rectal tumour is diagnosed in order to exclude any synchronous tumours. About 4% of patients diagnosed with primary colorectal cancer will have synchronous colon cancers. Colonoscopy enables direct visualization of the tumour and its extent with assessment of its fixity to the surrounding tissues; and its potential for complete obstruction. In addition, biopsies can be taken and any significant active bleeding can be controlled.

Imaging

Accurate identification of metastatic disease is key for the decision to operate on a patient. CT colonography and barium enema can be used instead of colonoscopy for the initial diagnosis of the tumour. For colon cancer, a CT scan is used to stage local disease and assess for potential distant metastases (i.e. lung, liver). CT of the chest, abdomen and pelvis is usually requested. For rectal cancers MRI is used to stage local disease and CT to assess potential distant metastases. There is not enough evidence yet to support the regular use of positron emission tomography (PET) or PET/CT scans in this group of patients. It is therefore employed when clinical and radiological findings from other scans are equivocal. For low rectal cancers endorectal ultrasound has been used with high accuracy for the early stage cancers.

CT colonography

CT colonography is a modern application of the conventional CT scan that can provide information on the entire colon. It is minimally invasive and has been reported to be easier to tolerate by the patients. It is required that the patients undergo bowel preparation before the procedure, although more recent studies have been investigating the potential to avoid this. The side effect of this modality is the increased radiation that patients receive compared with conventional colonoscopy. Low radiation protocols are currently being investigated, with early results showing that it is feasible to provide good images. There have been three large multicentre studies published with significant differences reported in terms of the accuracy of CT colonography. Pickhardt *et al.* found comparable sensitivities between CT colonography (86%) and colonoscopy (90%) in the detection of polyps of ≥6 mm.

However, subsequent publications showed that colonoscopy was significantly superior to CT colonography by detecting up to 99% of lesions/polyps. A more recent study showed that CT colonography has high sensitivity (97%) and specificity (about 91%) and that it can be more accurate than barium enema studies, but less accurate than colonoscopy. A meta-analysis of 49 studies of 11 151 patients was performed to assess the sensitivity of CT colonography and colonoscopy and demonstrated high sensitivity for both tests with moderate between-study heterogeneity when both cathartic and tagging factors were combined for bowel preparation.

Barium enema

Barium enema is well established in the NHS in the UK. It is safe and readily available. Bowel preparation is necessary but there is no need to sedate the patient, and therefore the patient can be discharged home the same day. Barium enema on its own has lower sensitivity than colonoscopy, and any negative results should be interpreted carefully in association with the patient's symptoms. Another disadvantage of barium enema is the inability to take tissue biopsies or remove any polyps. For these reasons its use has been declining in NHS centres where colonoscopy or CT colonography is available.

Locoregional staging

Computed tomography

CT is extensively used in the preoperative assessment of patients with colorectal cancer. It is used to assess local and distant disease. Studies have shown variability in the assessment of the extent of local disease. Modern CT scanners can also provide detailed reconstructed three-dimensional images that can help to improve the interpretation of two-dimensional images. A recent study has demonstrated that modern CT scanners are highly accurate in predicting the pathological T stage (pT). The diagnostic accuracy for T2 and T3 was 94.1%, and 100% for T4 tumours. The same study demonstrated high diagnostic accuracy (80.5%) for detecting lymph node metastases. In older studies, CT was less accurate in detecting and staging tumour and lymph node metastases.

A large study demonstrated that lymph node metastases were often missed by CT. This may be because of the weakness of CT to detect micrometastases and microalterations of the lymph node shape and size. In order to address this, Kanamato *et al.* analysed every lymph node that was detectable by CT and measured its longest and shortest diameter. They demonstrated that a short–long-axis diameter ratio of 0.8 or greater as an index for the diagnosis of metastatic lymph nodes achieved an accuracy index of 80% per node. As the technology evolves, it is likely that CT scanners will become even more accurate. There are radiological criteria for CT that have been established in order to facilitate radiological staging. The criteria are described in Table 30.13.

Table 30.13 CT criteria for colonic T staging

Stage	Description
T1	Intraluminal lesion without evidence of bowel wall invasion (bowel wall thickening)
T2	Thickened colon wall without disruption of muscularis propria
T3	Thickened colon wall with discrete mass extending into pericolic fat
T4a	Irregular advancing edge of tumour penetrating adjacent organs
T4b	Breach of the peritoneum that covers the colon
T4c	Perforated tumours with evidence of pericolonic gas and free fluid in the abdomen

Magnetic resonance imaging

MRI is the investigation of choice for pretreatment local (T) staging for rectal tumours. High-resolution MRI can clearly depict the bowel layers and accurately detect the depth of tumour invasion, extramural invasion and the relationship of the tumour to the surrounding anatomical structures. MRI has high diagnostic accuracy in predicting the T stage and the distance of the tumour from the circumferential margins. It correctly anticipates the subsequent histopathological examination in 85% of T3 and T4 tumours. MRI has a sensitivity of 94% and a specificity of 85% in determining the relationship between the advancing border of the tumour and the fascia propria of the rectum. Involvement of the fascia propria predicts a positive surgical circumferential margin. MRI also allows the subcategorization of T3 tumours into T3a and T3b.

Nodal staging has been always challenging as micrometastases may not be diagnosed. Nodal staging, whether assessed by ultrasound or MRI, is still unreliable, but analysis of the consistency of the node and the regularity of its capsule as demonstrated on MRI may improve its accuracy. Brown *et al.* showed that the heterogeneity of the lymph node's MRI signal was a highly specific discriminator, raising the diagnostic sensitivity to 85% and specificity of 97%. A recent study by Kim *et al.* showed the diagnostic accuracy of MRI to be 83% in detecting lymph node metastases compared with the 70% accuracy of PET. Combining both modalities increased the diagnostic accuracy to 90%. More recently, the use of nanoparticle-enhanced MRI (using ultrasmall superparamagnetic iron oxide as a contrast agent) is reported to have sensitivity in the order of 92% and specificity of around 96% for detecting lymph node metastases.

Imaging for distant metastases

Identification of distant metastases is crucial in the management of patients with colorectal cancer as it drastically changes the management of patients. CT and MRI have demonstrated high sensitivity in detecting distant metastases, providing detailed anatomical information of the affected organ and tumour extension into surrounding tissues (Figure 30.48a,b).

A meta-analysis investigating the value of ultrasound scan (USS), CT, MRI and PET in detecting liver colorectal

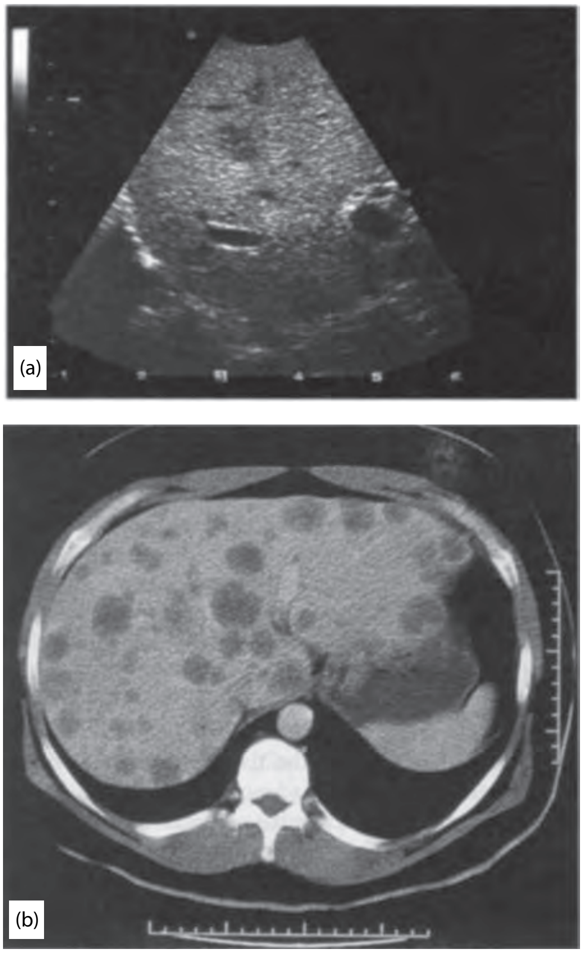

Figure 30.48 (a) Ultrasound appearance of hepatic metastases – image obtained at intraoperative contact ultrasound. (b) CT scan showing multiple hepatic metastases.

metastases demonstrated a sensitivity of 63%, 74.8%, 81.1% and 97.2% respectively and specificities of more than 93.8%, with MRI being significantly more sensitive than CT ($p=0.05$) and equally sensitive to PET ($p=0.02$). There was no significant difference in the sensitivity of PET and CT ($p>0.05$) and neither between CT and USS ($p=0.45$). Contrast-enhanced CT and gadolinium-based enhanced MRI can improve the diagnostic accuracies of CT and MRI respectively.

The incidence of lung metastases secondary to colorectal cancer (about 5% of colorectal cancers) is not as high as liver metastases. Therefore the regular use of chest CT may be questioned. In the UK, it is standard practice to perform a chest CT when staging patients with colorectal cancer. A recent study investigating the CT scans of 619 patients demonstrated high sensitivity (83.9%) and specificity (99%) for modern CT scan in detecting lung metastases. MRI is not used routinely to look for lung colorectal metastases, even though its diagnostic accuracy is similar to CT. It can be used when the findings of CT are equivocal; however, with the introduction of PET/CT, its role has been limited for staging the lungs.

PET has been demonstrated to be highly accurate in the detection of disseminated disease. A meta-analysis reported a PET sensitivity of 91% and specificity of 83% for the diagnosis of distant metastases. However, the authors admitted that only eight of 27 (29.6%) studies were of high quality, fulfilling their quality criteria at least by 80%.

Histopathological staging

In the UK Dukes' staging is still used to stage most bowel cancers. The original Dukes' classification was based entirely on pathological examination of the level of invasion in the resected specimen (Table 30.14). In spite of Dukes' concerns about the accuracy of surgeons' observations, it is now common practice to combine pathological staging with clinical assessment. Turnbull, who defined Dukes' stage D as any patient with metastatic or residual local disease, first introduced this clinicopathological staging in 1967. Others have defined Dukes' stage D as any metastatic disease in the abdomen alone or any systemic or residual local disease. In order to overcome the shortcomings of Dukes' classification, TNM systems are increasingly being applied to stage colorectal cancer patients.

TNM staging system

The TNM system was first introduced by Pierre Denoix between 1943 and 1952. In 1958 the first recommendations were published for the clinical stage classification of cancers of the breast and larynx. In 1968 the International Union Against Cancer described the classification of 23 body sites, and in 1974 and 1978 the second and third editions were published containing new site classifications. Over the years, amendments to previously published classifications have been made up to the present seventh edition of the TNM, containing rules of classification and staging that correspond with those of the American Joint Committee on Cancer's *Cancer Staging Manual*. The TNM classification system describes the anatomic extent of cancer. It is based on the fact that the choice of treatment and the chance of survival is related to the extent of the tumour at the primary site (T), the presence or absence of tumour at the regional lymph nodes (N), and the presence of metastasis beyond the regional lymph nodes.

Tumour staging can be classified prior to treatment, i.e. clinical staging (cTNM), and after resection, i.e. pathological TNM (pTNM). In cases where patients underwent preoperative chemoradiotherapy, the pathological staging is denoted by the prefix 'y' such as ypTNM. T is usually divided into four major parts (T1–T4), expressing different size or spread of the primary tumour. N and M have at least two categories each (0 or 1 indicate the absence or presence of tumour). A tumour with four degrees of T, three degrees of N and two degrees of M will have 24 TNM categories and for this purpose it is often necessary to condense these categories into a convenient number of TNM

Table 30.14 Initial Dukes' stage

Dukes' A	Invasion into but not through the bowel wall
Dukes' B	Invasion through the bowel wall but not involving lymph nodes
Dukes' C	Involvement of lymph nodes
Dukes' D	Distant metastasi(e)s

Table 30.15 TNM stage grouping for patients with colorectal cancer

Tumour	Lymph node	Metastasis
Stage 0		
Tis	N0	M0
Stage I		
T1	N0	M0
T2	N0	M0
Stage II		
T3	N0	M0
T4	N0	M0
Stage III		
Any T	N1	M0
Any T	N2	M0
Stage IV		
Any T	Any N	M1

stage groups. The purpose of the adopted grouping is to ensure that each group is more or less homogeneous with respect to survival and differs for colorectal cancer. The severity of disease, for example the extent of cancer spread (staging), has been well documented as an important determinant of long-term outcome (Table 30.15).

Medical treatment

Each individual case must be discussed in a multidisciplinary setting before any decision for medical or surgical therapy is made. Medical therapy can be in the form of neoadjuvant (preoperative), adjuvant (postoperative) or palliative, chemotherapy or chemoradiotherapy.

Neoadjuvant therapy

Neoadjuvant radiotherapy

Neoadjuvant radiotherapy or chemoradiotherapy is the most common application of preoperative medical therapy in colorectal cancer. It is mainly used for high-risk rectal cancer, when the margins are threatened or when a tumour response may change the type of surgery required to achieve complete clearance (perform an anterior resection instead of abdominoperineal resection) and preserve the anus and bowel function. Neoadjuvant chemoradiotherapy is used for T3, T4, lymph node-positive disease, and when the resection margins are threatened. For chemoradiotherapy, capecitabine and bevacizumab are the chemotherapeutic agents that are commonly used to increase the tumour's sensitivity to radiation.

Studies have shown that neoadjuvant chemoradiotherapy can reduce the local recurrence rate without changing the overall survival rates. A meta-analysis of randomized controlled studies with patients who underwent neoadjuvant therapy prior to surgery for resectable rectal cancer showed a marginal benefit for neoadjuvant radiotherapy that did not reach statistical significance. The same study showed that the cancer-specific survival and local recurrence rate were reduced in the group of neoadjuvant radiotherapy. In a more recent study the use of preoperative short-term radiotherapy reduced the 10 year local recurrence by more than 50% without an overall survival benefit.

Neoadjuvant chemotherapy

Chemotherapy prior to surgery is used to reduce the tumour's size so that it can be resected with higher likelihood of complete resection and fewer operative complications. 5-Fluorouracil (5FU) is the first-choice chemotherapy drug for colorectal cancer and is used intravenously. It can be used in combination with leucovorin (folinic acid) that has been shown to increase its action. More recently the same medication has been developed in a form that can be taken orally (capecitabine).

There are new chemotherapeutic agents that can be combined with 5FU or used alone. These include irinotecan, oxaliplating, cetuximab and penitumumab. These, apart from cetuximab, are usually used in combination with 5FU.

Preoperative chemotherapy has not been extensively used for patients in whom surgery is likely to completely remove the primary cancer. There is currently an ongoing randomized controlled study in the UK that is investigating the value of neoadjuvant chemotherapy in patients who would otherwise undergo colonic surgery and adjuvant chemotherapy (FOxTROT). This study is based on the observation that in other cancers preoperative chemotherapy has proved to be more effective than postoperative chemotherapy. This has generated the following hypotheses:

- Early optimal systemic therapy may be more effective at eradicating distant metastases than the same treatment given after the delay and immunological stress of colonic surgery.
- Shrinking the primary colon tumour before surgery may reduce the risk of incomplete surgical excision, and the risk of tumour cell shedding during surgery.

Adjuvant medical therapy

The aim of adjuvant chemotherapy is to prevent the dissemination of the disease in high-risk patients. This is discussed at the local multidisciplinary meetings with the results of the histopathology. Adjuvant chemotherapy has been shown to increase the overall survival and disease-free survival.

These are the factors that are considered to increase the risk of dissemination and used as an indication for adjuvant chemotherapy:

- positive lymph nodes
- poorly differentiated cancer cells
- vascular and perineural invasion
- T4 cancer
- evidence of localized distant metastasis during the operation.

Chemotherapy regimes that are currently in use are the following:

- FOLFOX – leucovorin, 5 Fu and oxaliplatin
- XELOX – a combination of oxaliplatin and capecitabine
- capecitabine/5 Fu
- tegafur and uracil capsules.

Palliative therapy

Radiation and chemotherapy have been used in patients who have irresectable (tumour that cannot be resected) or inoperable (tumour that is not indicated to be operated due to dissemination) disease. Radiotherapy is usually used to alleviate symptoms related to tumour expansion such as pain, lower leg oedema and lymphoedema. The aim is to shrink the tumour and reduce the effect to the local tissues. Systemic chemotherapy is used to control the dissemination of the disease and prolong the overall survival. A meta-analysis of seven trials with 866 patients showed a 35% reduction in the risk of death and 16% in the improvement of survival within a year when palliative chemotherapy was used. There was also an improvement of survival by 3.7 months (median).

Surgical treatment

Colon cancer surgery

Historical perspective

The intestinal suture was considered a 'mighty procedure in a highly vulnerable organ', and therefore a dangerous option for surgery. The formation of a stoma used to be the surgical treatment of choice for any intestinal disease and injury. Colostomy was introduced as a palliative procedure for patients with obstructive bowel cancer in 1839. Until then, patients diagnosed with obstructive cancer would have either died or been relieved by a spontaneous fistula.

Reybard of Lyons in 1833 was the first to perform a successful resection of the sigmoid colon, but he found great opposition from the Paris Academy of Medicine. The mortality following a colonic resection ranged from 60% before 1889 to 37% by 1900. Owing to the high mortality rates the staged extraperitoneal resection technique (exteriorization–resection) was usually employed.

Bowel resection with anastomosis was not widely performed until the introduction of antibiotics. The sigmoid colectomy was always performed with the formation of a defunctioning colostomy until the 1950s. At that time, the interest of the surgical community was focused on ways to reduce faecal contamination during the procedure. A number of published articles discussed the application of non-crushing clamps and the value of limited inversion of the anastomosis. Stapling techniques were reported as early as 1908, but they have found widespread application more recently.

Procedures

The aim of surgery is to achieve complete tumour resection with an adequate resection margin, along with draining the lymphatics and the creation of a tension-free anastomosis.

The following operations are performed for colon cancer:

- right colectomy
- transverse colectomy
- left colectomy
- sigmoid colectomy
- sutotal/total colectomy
- palliative resection (limited).

The majority of the new surgeons prefer to perform colon operations through a midline incision, the extent of which (upper, lower or full extent) is dictated by the type of colectomy, position of the tumour and body habitus. The advantages of a midline incision are the following:

- it facilitates quick entrance into the peritoneal cavity
- it provides adequate access to both sides of the abdomen
- it allows the formation of either a colostomy or ileostomy to either side
- the wound heals strongly and is easily closed in a single layer.

A right-sided oblique incision may be employed for right colon resections. The wound from this type of incision heals well and is possibly associated with less discomfort for the patient. However, the exposure may be compromised. This type of incision is mainly used by older surgeons who had been trained to do this technique, as previously it was more widely used. The introduction of minimally invasive surgery resulted in this technique being abandoned. Minimally invasive surgery enabled faster bowel function recovery and feeding of patients. This was associated with less discomfort and shortened hospital stay.

These results led to the introduction of minilaparotomy. Minilaparotomy has been defined as complete resection performed through a skin incision less than 7 cm long. Minilaparotomy for colon cancers was shown to be feasible, with comparable oncological outcomes, and was found to reduce hospital stay and analgesia requirements. Body habitus was found to be a crucial factor in the completion of the procedure without extending the incision.

When the peritoneal cavity is entered, it is important to check for the presence of metastatic liver and/or lymph node disease and peritoneal dissemination. The tumour is examined at the end after excluding dissemination of disease. Resectability and fixation of the tumour to the surrounding tissues are evaluated with minimum handling. Large lymph nodes can be inflammatory and, when in doubt, a frozen section can be sent for histopathological examination.

Right hemicolectomy

Right hemicolectomy is performed to resect lesions located at the caecum, ascending colon and hepatic flexure. The blood supply in this area originates from the ileocolic and right colic arteries, and therefore dictates the use of right hemicolectomy. The positioning of the surgeon is a matter of personal preference. The small bowel is retracted into the left upper quadrant of the abdominal cavity, exposing the root of the mesentery and the base of the transverse mesocolon.

The right colic and right branch of the middle colic vessels may be ligated at the beginning of the dissection. This can be more challenging in the obese patient and may not be safe to perform. The small incision in the root of the mesentery is extended to the point that the transverse colon will be divided. The mesenteric and mesocolic vessels are ligated, limiting the entire blood supply to the tumour. In more recent years, the implementation of vessel-sealing devices has changed the way that this part of the procedure is performed. These devices can securely seal small vessels (up to 7 mm diameter) within a few seconds. This technique can replace the use of clips and sutures.

The congenital peritoneal adhesions along the lateral gutter are divided using coagulation diathermy, elevating the terminal ileum and right colon from the retroperitoneal structures. This will include any lateral peritoneum involved by serosal tumour with the specimen. Care must be taken to avoid injury to the ureter, spermatic or ovarian vessels, and inferior vena cava. The ileocaecal fold of Treves is incised to prepare the terminal ileum. As the colon is elevated from the retroperitoneum, the second part of the duodenum will appear and should be displaced with care to avoid any injury. The hepatic flexure is freed from the developmental gallbladder and liver adhesions using diathermy or vessel-sealing devices. When the colon is sufficiently lifted the head of the pancreas will be visible indicating that the duodenum is adequately cleared from the field. Clamping of the blood supply can be safely performed now following development of the avascular plane around the vessels.

The lesser sac is entered by dividing the greater omentum, enabling at the same time the retraction of the posterior wall of the stomach away from the dissecting field and therefore reducing the risk of injury. The dissection of the greater omentum continues until the hepatic flexure is fully mobile. The omentum is incised at the point of the anastomosis. The bowel is therefore ready for resection. On rare occasions that the tumour invades the duodenum and the pancreas the tumour can be resected *en bloc* with the duodenum and pancreas (pancreaticoduodenectomy). This will require the employment of an expert hepatobiliary surgeon.

Surgery for transverse colon cancer

Cancer of the transverse colon can often be a challenge for the colorectal surgeon. The blood supply to this area is derived from the middle, right and left colic vessels and an anastomosis at the splenic flexure may beat risk of ischaemia, as the blood supply solely from the inferior mesenteric artery may not be sufficient. This is not usually an issue when dealing with tumours at the hepatic flexure, as there is sufficient blood supply from the ileocolic and right colic vessels.

The lymphatic drainage is also an issue when dealing with tumours of the transverse colon. Cancer in the transverse colon can metastasize to regional lymphatics through the middle colic, right colic and left colic branches. This is why some surgeons suggest subtotal colectomy as an option for this type of cancer. Other surgeons decide the type of surgery based on the location in the transverse colon, suggesting right hemicolectomy for proximal lesions and left partial or left hemicolectomy for distal lesions. For the latter the anastomosis can be performed between the transverse and the sigmoid colon. This will require mobilization of the right colon as well. Limited transverse colectomy may be considered for palliation. As mentioned, however, as a cancer operation it may be inadequate. Mobilization of the splenic flexure and left colon are explained in the section Rectal cancer surgery. The same principles are applicable here.

When the tumour invades the spleen or when the spleen is at risk, *en bloc* splenectomy may be indicated. In these circumstances the spleen and tail of the pancreas may need to be removed *en bloc* with the colon. Splenectomy in association with colonic resection for cancer is associated with a high morbidity and mortality rate. The incidence of unintentional splenic injury during mobilization of the splenic flexure is around 1%. Splenectomy increases the rate of postoperative sepsis in this group of patients.

Left hemicolectomy (partial colectomy)

Left hemicolectomy is performed for tumours involving the distal transverse colon, splenic flexure and descending colon. In this procedure, the proximal right branch of the middle colic and the inferior mesenteric artery should be preserved. The left colic artery is ligated. The anastomosis is performed between the mid-transverse and the upper sigmoid colon. The technique of the mobilization is described in the section Rectal cancer surgery.

Subtotal/total colectomy

Subtotal colectomy involves the removal of most of the colon with an anastomosis between the ileum and the sigmoid or descending colon. Total colectomy involves the removal of the entire colon with an ileorectal anastomosis at the rectosigmoid junction. It is a more extensive operation with the advantage of an easier to perform anastomosis and maximum harvesting of lymph nodes. Subtotal or total colectomy may be indicated for the following:

- synchronous left- and right-sided tumours
- multiple tumours (benign or malignant or both) are present
- FAP and IBD
- HNPCC
- when a resection has been previously performed
- technical limitations.

Complete mesocolic excision

Surgery for rectal cancer has become standardized with the implementation of TME. Until recently, there had not been any attempts to standardize surgery for colon cancer. Hohenberger *et al*. suggested the equivalent to the TME procedure, the complete mesocolic excision (CME) of the colon. The concept of CME is based on the same embryological principles of TME. It involves sharp dissection of the visceral plane from the retroperitoneal one with high ligation of the draining/supplying vessels, aiming to prevent any injury of the visceral fascia layer that may potentially result in spillage of tumour cells and dissemination of the disease.

For right colon cancers the mobilization of the duodenum with the pancreatic head (Kocher manoeuvre) and the mesenteric root up to the origin of the superior mesenteric artery is essential to maximize the exposure of the supplying vessels. The attachments of the mesenteric plane to the duodenum and the uncinate process are dissected in order to gain full access to the superior mesenteric vessels. The right colon is fully mobilized and therefore can be twisted (clockwise) to provide easier access to the central part of the superior mesenteric vessels. The ileocolic and, when present, the right colic vessels should be divided at their origin from the superior mesenteric vessels. For caecal and ascending colon cancer, ligation of the right branches of the middle colic vessels is adequate. The colon is divided at the level of the middle colic vessels. For hepatic flexure cancer, the transverse colon is resected at the splenic flexure.

For transverse colon cancers, the proximal part of the colon can be preserved and anastomosed to the sigmoid colon. The right colic vein drains into the superior gastroepiploic vein. It is usually ligated first to prevent severe haemorrhage from accidental injury. The superior mesenteric vessels are subsequently exposed, as the veins supplying the arteries are divided centrally. Attempt should be made to preserve the surrounding autonomous nervous plexus to avoid the risk of bowel dysfunction. If there are suspicious pancreatic lymph nodes they can be dissected off the pancreatic head with central ligation of the right gastroepiploic artery. The superior pancreaticoduodenal artery is usually preserved.

For left colon tumours, mobilization of the splenic flexure with the left colon is performed. This is described in more detail in the section Rectal cancer surgery. Once the left colon is completely dissected off the retroperitoneum, the greater omentum is divided from the transverse colon to facilitate full exposure of the lesser sac and the subsequent division of the final two layers of the transverse mesocolon at the lower edge of the pancreas. It is important that during this process the integrity of the mesocolon is maintained in a similar way to the mesorectal excision for rectal cancer. The root of the inferior mesenteric artery is usually preserved. The left colon artery is centrally ligated including the lymph nodes at the origin of the inferior mesenteric artery. Preservation of the superior hypogastric plexus is also important.

For cancers of the mid-descending colon down to the sigmoid colon, the root of the inferior mesenteric artery and the inferior mesenteric vein below the pancreas are ligated. The proximal colonic division is performed at the point between the left transverse colon and the proximal descending colon and depends on the tumour site. The resection is performed distally in the upper third of the rectum.

The implementation of CME can significantly increase lymph node harvesting. Hohenberg *et al.* harvested a median of 32 lymph nodes. The same study showed that in patients with N0 disease ($n = 314$) the 5 year survival was improved by almost 6% when the number of harvested lymph nodes was 28 or more (96.3% vs 90.7%). This difference was shown to be statistically significant ($p = 0.018$). The same conclusion was drawn for patients with positive lymph nodes ($n = 383$). There was an improvement in the 5 year survival by 6.1% when the number of harvested lymph nodes was 28 or more (71.7% vs 64.6%). This however did not reach statistical significance ($p = 0.088$). The cut-off of 28 lymph nodes was found to be an independent predictive factor in disease-free survival. At present, there are no clear guidelines about which colonic tumours are suitable for an open CME approach vs a laparoscopic colectomy. A 'low-risk' right colon cancer (T1, T2, T3a/b, node negative, extramural venous invasion (EMVI) negative) may be best managed with a standard laparoscopic right hemicolectomy. CME surgery may be reserved for 'high-risk', T3c/d, T4, node-positive, EMVI-positive colon cancers where a high nodal dissection may be indicated to maximize the oncological clearance of such cancer.

Wound closure

Abdominal wall closure depends on the surgeon's preference. In the UK a loop 0-PDS or 0-nylon suture is commonly used for mass closure using a continuous technique. Other sutures such as polyglyconate can be used. There is no evidence in the literature to suggest significant differences between the above sutures in terms of wound infection rates, dehiscence and hernia formation. The skin is closed either with clips or with a 3/4-0 monocryl subcuticular suture.

Rectal cancer surgery

Historical perspective

The first attempts to surgically treat rectal cancer took place during the nineteenth century, when Giovanni Morgagni was the first to suggest that resection of the rectum could be used as a treatment of rectal carcinoma. Operating at that time was performed without general anaesthesia and haemostasis, increasing significantly the rates of mortality and morbidity. The first two reported resections were unsuccessful and the patients did not survive the operation.

The first attempt to resect the rectum was performed in 1739 by Jean Faget, who intended to drain an ischioanal abscess but instead found a perforated rectal cancer. The patient died following the operation as he was left with an 'uncontrollable anus.' The second recorded attempt to resect an annular obstructing lesion also resulted in the patient not surviving the operation.

It was not until 1826 that the first successful resection of the rectum was performed by Lisfranc. This success was followed by five more successful operations from a total of nine that Lisfranc performed in the following years. These procedures were performed without anaesthesia and haemostasis, carrying significant risks of postoperative morbidity, with unbearable pain, sepsis and major bleeding being the commonest complications. During that era of surgery, the operation was considered successful if the patient was discharged home following the procedure. The patients who survived the operation would definitely return with recurrence and die.

The application of aseptic technique principles and the introduction of general anaesthesia enabled the performance of more advanced procedures, with Theodor Kocher proposing the transacral resection of the rectum, which was further developed by Paul Kraske, who aimed to improve the operative exposure. Carl Gussenbauer followed, using an abdominal approach to resect the tumour and Hochenegg used a 'pull-through' (duerchzug) technique to perform a rectoanal anastomosis.

Abdominoperineal resection

The first abdominoperineal resection was performed by Vincent Czerny in 1884, when the tumour could not be removed 'peritoneally' and the procedure had to be completed abdominally after turning the patient supine. Taking advantage of the larger operating field, Ernest Miles was the first to perform an 'anatomically correct' resection of the rectum removing the draining lymph nodes, at the same time combining the abdominal and perineal approach.

Using this technique, Miles reported a reduction in the recurrence rate to 29.5%. The most common complications were sepsis and blood loss resulting in a mortality rate of 31% as blood transfusion and antibiotics were not yet available. The patient's quality of life was significantly impaired, since the formation of colostomy was standard practice at the time, and the extensiveness of the procedure meant that the autonomic nerve plexuses were damaged and consequently sexual and urinary function would be adversely affected. Many surgeons suggested that the Miles procedure was too radical, carrying significant risks of genitourinary and bowel dysfunction with adverse psychosocial implications. This led Cuthbert Dukes (Dukes' classification of colorectal tumours) to further investigate the resected specimens following the Miles procedure and demonstrate that Miles overestimated the tumour spread within the regional lymph nodes and that the majority of lymph nodes were close to the level of the primary tumour. The modern abdominoperineal resection involves an extralevator dissection, which involves detaching the levator ani muscles from their insertion at the lateral pelvic sidewall. The posterior insertion of the levator ani muscles can be detached by removing the coccyx and extending the dissection proximally by lifting the presacral (Waldeyer's) fascia off the distal sacrum *en bloc* with the resected specimen. This has recently been popularized as the 'prone extralevator APER (abdominoperineal excision of rectum)', although the same oncological clearance can be obtained with the patient in the Trendelenburg position.

Anterior resection

As a result of the poor quality of life following surgery, surgeons had started to focus on less radical resections that led to the now widely established anterior resection. Donald Balfour described the technique of the anterior resection with the performance of an end-to-end anastomosis. Dukes' findings about Miles' overestimation of tumour spread led surgeons to investigate further the potential of anterior resection as an alternative for cure, with the advantage of maintaining bowel continuity. Anterior resection was not widely adopted until 1948, when Claude Dixon demonstrated that it was safe to perform with an improved mortality and 5 year survival rate of 2.6% and 64% respectively. Anterior resection was only performed for tumours that were more than 5 cm above the anal verge, as it was believed at the time that 5 cm distal margins were essential to achieve a curative resection. The possibilities for further development of anterior resection were realized after a study demonstrated that distal margins up to 2 cm do not compromise the oncological result in terms of survival and local control. Sphincter preservation procedures were the standard in cases where the sphincter was not directly involved by the tumour. In 1986, the creation of a colonic pouch combined with coloanal anastomosis was proposed, and improved bowel functional outcomes.

Total mesorectal excision

In the late twentieth century, Professor Heald popularized the technique of TME based on the embryological development of the hindgut, after studies demonstrated that resection margins of 2 cm should be considered as safe. Professor Heald initially suspected the value of the mesorectum in 1982, which led him to further investigate the 'holy plane' around the embryological hindgut and propose a standardized oncological rectal surgery by performing TME of the rectum, which could potentially improve the oncological outcomes while preserving the sphincter. In 1992, he successfully demonstrated that TME significantly reduced the local recurrence rate, especially for patients with Dukes' B and C stage cancers. These, along with the findings that a 2 cm distal surgical margins is sufficient, have probably been the most significant milestones in rectal cancer surgery, and led surgeons to widely adopt the technique of TME, welcoming the option to preserve the sphincter and bowel function without compromising the oncological outcome.

Extended lateral pelvic sidewall lymphadenectomy

Between 30% and 40% of patients treated for rectal cancer present with lymph node metastases. These can occur either along the mesorectal nodal chain along the inferior mesenteric artery nodes in around 40% of patients, and/or to the lateral pelvic lymph nodes (along the obturator, internal iliac and medial aspect of the external iliac artery) in 10–25% of patients. The presence of lateral lymph node metastasis in rectal cancer was first reported in the 1950s, and nodal involvement has subsequently been shown to be associated with a poorer prognosis, higher incidence of local recurrence and reduced survival.

In Western countries, TME has become the operation of choice for low rectal cancer. The technique is associated with a low incidence of local recurrence and facilitates sparing of the pelvic autonomic nerve plexuses. With the introduction of neoadjuvant radiotherapy combined with TME, local recurrence rates of less than 10% have been achieved. Western surgeons do not utilize extended lymphadenectomy regularly, and this may pose a risk of local recurrence in the pelvic sidewall in patients who have undergone potentially curative surgery without preoperative radiotherapy. Whether pelvic sidewall lymph nodes should be considered metastatic disease or part of the regional lymphatics is a contentious issue.

Based on the above, Japanese surgeons have adopted the technique of extended lymphadenectomy to supplement TME, aiming to minimize local recurrence and improve survival. The disadvantages of extended lymphadenectomy include increased rates of autonomic nerve dysfunction such as urinary and sexual impairment and intraoperative adverse events. There has also been interest in neoadjuvant radiotherapy in addition to TME and Nagawa *et al.* showed that the addition of extended lymphadenectomy to surgery, when neoadjuvant radiotherapy had been previously applied, did not significantly alter the local recurrence and survival rates.

Japanese surgeons proposed the lateral pelvic sidewall lymphadenectomy as an additional procedure to standard rectal cancer surgery, with a number of studies demonstrating controversial results. The introduction of neoadjuvant radiotherapy to the management of rectal cancer came late in the twentieth century, demonstrating reduced recurrence rates but without any significant impact on the patients' survival.

All the efforts of these great surgeons have significantly changed the management of patients with rectal cancer, improving oncological outcomes and quality of life. However, the recurrence rates following curative resection of the primary tumour are still considered high, necessitating more radical resection (exenterative procedures), such as abdominosacral resection of the rectum and total pelvic exenteration, which involves the removal of the adjacent pelvic organs and structures.

Survival and local recurrence

The main goal of surgery for rectal cancer is to achieve complete tumour removal with minimal complications and acceptable urinary, bowel and sexual function. The improvements in surgical technique and the awareness of the importance of adequate excision margins has enabled improvement of oncological outcomes by achieving higher rates of complete tumour removal (R0 resection), which is reflected in the reduction of locoregional failure rates. Although surgery and radiotherapy play a crucial role in the ultimate outcome, it appears that tumour pathology is the most important factor for overall and local recurrence-free survival.

Local excision for rectal cancer

The original criteria for local excision included small tumours (Dukes' A) of the rectum, which were mobile and accessible to endoanal removal. Morson *et al.* amplified the purely clinical criteria of Lockhart-Mummery to include two phases: the clinical assessment and the subsequent histopathological findings after removal. These included complete microscopic excision, tumour confined to the rectal wall, absence of lymphovascular invasion and a well-differentiated tumour. In patients having a local excision based on the clinical criteria of size under 3 cm, mobility and the 'feel' of being confined to the rectal wall, the final therapeutic decision would be determined by the pathology. If the above histopathological circumstances were not fulfilled, the patient was advised to undergo total anorectal excision.

The present

Local excision has been used for cure or for palliation. In the latter, it can be applicable in patients with disseminated disease or in those with comorbidity precluding major surgery or in the elderly, provided in both cases that the tumour itself is small enough and sufficiently localized to the rectal wall to allow local excision to be technically possible.

The rationale for local excision is that a tumour confined to the rectal wall has a low likelihood of having simultaneous lymph node metastasis. Only a few patients are amenable to local excision for cure and make up only about 5% of the total number presenting with rectal cancer. They must be selected very carefully.

Over the last 20 years, two schools have developed in regard to local excision. The first has reduced the indications of those of Morson to include only T1 or a few so-called favourable T2 tumours. The second has explored the use of adjuvant radiotherapy in combination with local excision for growths of T2 or even T3 stages.

Pathology

Local excision is based on the premise that a tumour of early stage, for example T1 or T2, will have a low prevalence of regional lymphadenopathy. Thus, local excision removing the growth in its entirety according to the subsequent pathological examination would be sufficient to cure the tumour. The prevalence of regional lymphadenopathy for each T stage is therefore one key to case selection and the appropriateness or not of local excision. The best data available are those derived from the Erlangen Tumour Centre and University of Surgical Clinic 1986–1990. Hermanek studied the incidence of regional lymphadenopathy for each pT stage in a large series of patients undergoing major resection of rectal cancer. Similar rates for T1 (10%) and T2 (17%) were reported by Blumberg *et al.* The incidence of regional lymph node metastases by depth of tumour penetration are shown in Table 30.16.

In the light of these data, it is clear that local excision would result in up to a fifth or more of tumours confined to the rectal wall (T1 and T2) being inadequately removed owing to the presence of regional lymphadenopathy. Even in the T1 category, where the tumour is sessile, the Haggitt staging system has shown regional lymphadenopathy to be present in 10% or less of Sm1 and Sm2 tumours but in as much as 25% for Sm3 stage.

The second pathological consideration is that of the morphology of the tumour. This has received little attention, but the difference in cancer-specific outcome after local excision of exophytic and non-exophytic carcinomas is significant. In a series of 91 patients followed for 5 or more years, local excision of an exophytic carcinoma (polypoid, 30 sessile non-ulcerated, 26) resulted in a cancer-specific 5-year survival rate of 100% compared with 71% for a non-exophytic carcinoma (ulcerated, 15; flat raised adenocarcinoma, 20). Exophytic morphology was more likely to be associated with an earlier T stage with 48 (86%) of the 56 exophytic and only nine (26%) of the 35 non-exophytic carcinomas being of stage T1. Three (5%) of the 56 in the former group and nine (26%) of the 35 in the latter were stage T3.

Based on these facts, local excision as the only therapeutic modality should be offered for T1 tumours with exophytic morphology. These attributes are most likely to be found in a mobile tumour of 3 cm or less in diameter with well-differentiated

Table 30.16 Incidence of regional lymph node metastases by depth of tumour penetration

pT stage	*n*	Lymph node metastases (%)
T1	102	4.9
T2 (inner muscularis propria)	201	17.9
T2 (outer muscularis propria)	261	26.8
T3 (slight <1 mm)	278	45.7
T3 (extensive)	505	69.9
T4 (other organ involvement)	153	71.9
T4 (serosal penetration)	88	85.2

histology. It is still essential to adopt the combined clinical and histopathological policy whereby any excised tumour with incomplete excision, deeper penetration of the rectal wall than T1, lymphovascular invasion or poor differentiation should be discussed with the patient regarding subsequent major surgery.

Case selection

Based on the above criteria, the means of case selection include digital examination, endorectal ultrasound and MRI. Digital examination should not be underestimated. It is clear that it is not as accurate as ultrasound, being subjective and relatively insensitive. Nevertheless, it is only through digital examination that the possibility of local excision is considered in the first place, and the method can identify the T1 or T2 tumour with an accuracy of around 70%. Only those tumours identified as being small and mobile will be referred for ultrasound with local excision in mind.

Ultrasound has an accuracy of over 90% in assessing penetration of the rectal wall (the interface between T2 and T3). In a study of 351 patients, its sensitivity and specificity were reported for all T stages. Ultrasound correctly staged 49 of 71 T1, 104 of 149 T2 and 92 of 131 T3 tumours. Overstaging in the T1 group occurred in 29% and in 13% for T2 tumours. In a series of 356 patients, sensitivity and specificity for stage T1 were 86% and 94% respectively. Thus ultrasound was able to identify 69–84% of T1 cases in these studies. MRI is inadequate for identifying T1 and T2 tumours. It has a sensitivity of 40–60% and specificity of just under 90%.

Nodal involvement is more difficult to determine preoperatively. Indeed, there is currently no reliable means of doing so. Thus the overall accuracy reported by Garcia Aguilar *et al.* was 68% for non-involved and 52% for involved nodes. Mackay *et al.* obtained sensitivity and specificity values of 67% and 90%. MRI may, however, be able to improve on these figures. The finding on MRI of an irregular border or mixed signal intensity within a given node was associated with nodal involvement by tumour in 92% and 91% of nodes showing these features compared with 6% and 8% of nodes when they were absent. Further data on this are required.

Summary

A combination of digital examination, endorectal ultrasound and MRI will be able to select the T1 tumour in 70% or more of patients with this T stage. The added features of small size, exophytic morphology, accessibility and absence of poor differentiation all contribute to identifying the rectal carcinoma suitable for local excision or transanal endoscopic microsurgery (TEMS).

Technique

Endorectal local excision or TEMS are now the preferred methods. In the past, some surgeons used the posterior approach (Kraske, or that modified by York Mason), but this has the disadvantage of opening up the anatomical envelope of the rectum, which is oncologically unsound and will also make any subsequent major surgery more difficult than if an endorectal removal had been carried out.

For low rectal lesions (within 3–4 cm from the anal verge) an anal retractor and good lighting (a head light is recommended) are necessary; a full-thickness disc of rectal wall including the growth and a 1 cm margin of normal rectum are removed. Lesions in the mid-rectum are more accurately removed using a TEMS approach or an anal SILS port (single incision laparoscopic surgery). The former technique remains the gold standard for local excision, as the equipment provides three-dimensional endoscopic vision and the specialized angled instruments facilitate accurate removal of the rectal lesion and closure of the rectal defect.

Histopathology

The specimen is then pinned out onto a cork lamina and placed upside down in a formalin pot to fix. The pathologist will thus be able to orient it and take sections from the deep and circumferential margins. The report will state the following: completeness of excision, the presence or absence of lymphovascular invasion, the degree of penetration of the rectal wall and the histological grade.

An incomplete or doubtfully complete removal will make resection advisable. It is reasonable to consider 2 mm of clear margin as adequate. The risk of lymph node involvement is mainly determined by T stage, the histological grade of differentiation and vascular and lymphatic invasion. When invasion is confined to the submucosa, lymph node metastasis is present in only 5% of cases, but this incidence rises to over 20% in T2 tumours (see above).

Poor differentiation has a high risk of lymph node metastasis. Hermanek found nodal involvement in 77% of poorly differentiated cancers. Nevertheless, high-grade tumours are particularly uncommon in early rectal cancer with an incidence of less than 5%. Lymphovascular invasion has been usually considered by most pathologists as an unfavourable feature, with an increased risk of lymph node metastasis. Submucosal lymphatics are often difficult to see and there is wide interobserver variation. In a series of 81 malignant polyps, the assessment of lymphatic invasion may sometimes be too subjective to draw any valid conclusion. In the same series, submucosal venous invasion was found to have no prognostic importance.

Where any of the above pathological features indicate likely failure of clearance locally or a high chance of lymphadenopathy to be present, the patient must be advised accordingly. The risk of local recurrence and lymph nodes metastasis must be balanced by the morbidity and mortality of surgery. The decision will depend on the patient's wishes in the light of discussion about the pathological and clinical prognostic factors. Discussion may then result in agreement whether or not to undertake a total anorectal excision.

Results

Local excision is an uncommon treatment, and most reports in the literature contain small numbers of patients often accrued over many years. Thus case selection in many instances will have been made before the introduction of endorectal ultrasound and more recent imaging.

Several useful series have been reported. In a large series from the Mayo Clinic of 234 patients including 93 with a T1 and 141 with a T2 tumour, local failure occurred in 19%.

Killingback reviewed 63 cases of local excision out of a total of 493 patients with rectal cancer treated between 1969 and 1984. After excluding 25 with a malignant polyp, nine of the remainder developed local recurrence and seven (18%) died. Of the nine failures only five were suitable for a salvage operation, of whom three died. Whiteway *et al.* in a report about local excision of an ulcerating carcinoma in 27 patients, found a cancer-specific mortality of zero when the policy of subsequent major surgery following pathological examination of the specimen had been fulfilled. Of 26 patients who survived the operation, two refused further surgery despite being advised to have it. Both died of cancer. In the remaining 24 patients, five underwent subsequent major surgery, two of whom died of cancer. Therefore, the overall failure due to cancer occurred in 8% (two patients). In a report of 110 patients treated at St Mark's Hospital from 1948 to 1973 by local excision, there were only six failures. This series was updated to 1984. Of 167 patients with reliable follow-up of over 5 years, 152 were available for analysis. The results emphasize the importance of histological grade. Thus, local failure occurred in only one (2%) of 56 well-differentiated tumours compared with 12 (19%) of 64 patients with a moderately differentiated tumour.

Using more limited criteria for case selection Hermanek and Gall reported on 249 patients with an early carcinoma of whom 53 patients underwent local excision. The 5-year survival rate in this group was 95%. Of 130 patients having a major resection for a tumour of the same T stage, the 5-year survival rate was 100%.

The question of whether major resection or local excision should be performed was considered further by Mellgren *et al.* They reported the results of local excision in 108 patients treated for a T1 or T2 rectal carcinoma. These were compared with 153 patients with T1N0 and T2N0 lesions treated with abdominal radical surgery. No patients had radiotherapy. Local recurrence after local excision occurred in 18% of T1 and 47% of T2 tumours. This rate was compared with zero for T1 and 6% for T2 tumours after radical surgery. The authors pointed out, however, that survival was little different between the two groups when the results of salvage surgery after failed local excision in line with the policy of Morson were taken into account.

A more recent comparison of outcome of T1 tumours treated by local excision or radical surgery was reported by the Memorial Hospital New York. Of a total of 319 patients with a T1 tumour treated over a 17-year period, 151 underwent local excision and 168 a radical resection. The tumour was located in the rectum, significantly higher in the latter group by 2 cm and the diameter was on average 4 mm greater. Follow-up was 48 (1–145) and 58 (2–192) months respectively. The actuarially estimated 5-year local recurrence rates were 15% and 3% respectively ($p < 0.01$) and cancer-specific survival rates were 93% and 97% ($p < 0.05$). The level of the tumour may have been a factor in these differences, but lymph node metastasis may also have been important since the incidence of nodal involvement in the radical surgery group was 18%.

The evidence therefore indicates that radical surgery is less likely than local excision to be followed by local treatment failure and longer survival. A similar conclusion was drawn by Naseimbeni *et al.* regarding local recurrence and overall survival. These data emphasize the degree of risk and the importance of case selection associated with local excision.

Local excision combined with adjuvant therapy

While one line of development of local excision has been to reduce the indications of local excision, some authors have combined it with adjuvant postoperative radiotherapy with or without chemotherapy in an attempt to expand them. In reviewing the results, it should be borne in mind that major surgery for T2 and early T3 tumours has a low rate of local recurrence.

With the exception of Bleday *et al.* who reported no cases of local recurrence among 21 T2 tumours at a follow-up of 40 months [although local recurrence occurred in two (25%) of eight T3 cases], the experience of others has been less satisfactory. Local recurrence after local excision of T2 tumours in patients followed from 41 to 73 months ranged from 14% to 24% out of a total of 162 patients. For 37 patients with a T3 tumour, the rate of local recurrence ranged from 23% to 40%.

It is difficult to interpret the results in some incidences since these are not controlled data, and exclusions were made in certain instances. For example, Steele *et al.* in reporting 161 patients with a T1 or T2 tumour undergoing local excision followed by postoperative chemoradiotherapy, 51 were excluded from analysis owing to a positive margin, leaving eight patients with local recurrence among the remaining 110 patients. These data are summarized in a review by Sengupta and Tjandra.

It should be remembered that, for tumours of these T stages (including the early T3 case), major surgery is likely to be curative and also that cure can be achieved by ultra-low anterior resection where the growth is in the lower third involving where necessary an intersphincteric dissection. The decision for local excision is therefore a matter of great responsibility for the clinician.

Transanal endoscopic microsurgery

TEMS uses a sophisticated rigid endoscopic system having binocular optics, suction and carbon dioxide insufflation with sealable ports on the instrument to enable the introduction of specially designed instruments. The sigmoidoscope is fixed to the operating table, which can be adjusted. Formal training is required to perform this procedure (Figure 30.49). The operating field views are excellent and all the instruments are available in right- and left-handed versions. A high-frequency electrode coagulator is used for cutting.

The technique is similar to conventional endoanal excision. The margin of the tumour is marked using coagulation at a distance of 10 mm from the edge of the tumour circumferentially. The incision is then made with the electrocutter, and haemostasis is achieved using coagulation diathermy as necessary. The tumour is removed with a full thickness of rectal wall. The subsequent defect is sutured together endoscopically. The sutures used in this procedure use a short length of thread and are fixed by silver clips rather than knots.

TEMS vs local excision for early low rectal cancers

Although TEMS is considered a better surgical technique than local excision, it cannot be used in ultra-low rectal cancers.

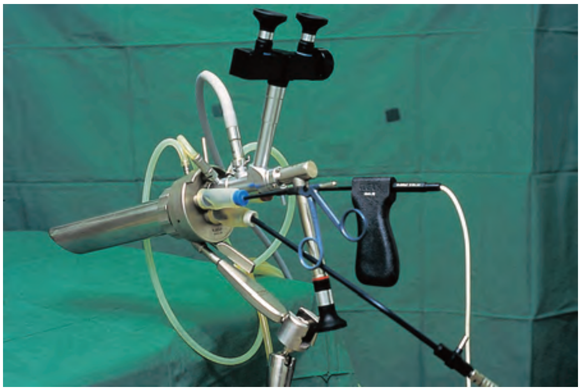

Figure 30.49 Buess operating protoscope for transanal endoscopic microsurgery.

Local excision may be a better option for this type of tumour. A recent study showed that the resection margins were more often positive in the local resection group (16%) than in the TEMS group (2%; $p = 0.017$) without any significant differences in terms of postoperative complications between the two groups. The authors of that study interpreted these results as to be related to the better quality of resection that was facilitated by TEMS. However, these results might be partly due to case selection bias, as lower risk tumours of the upper rectum were included in the study.

Two randomized controlled studies in Europe are currently investigating the differences of TEMS vs TME surgery, the results of which are not available. The reported local recurrence rates in the literature following TEMS and local resection are variable. Studies have reported local recurrence rates for TEMS ranging up to 13% for patients with T1 tumours and up to 80% for patients with T2 tumours. Similar rates have been reported for local excision, with local recurrence rates reaching up to 40% for patients with T1 tumours and up to 60% for patients with T2 tumours. TEMS may provide better views especially for higher rectal tumours, whereas local excision may be more suitable for lower rectal cancers

Total mesorectal excision

TME is currently considered the gold standard for the surgical management of low and mid-rectal cancer. It is still debatable whether a TME should be performed for upper rectal cancers, as there is not adequate evidence to support it. When the tumour involves or is close to the anal sphincter complex, abdominoperineal resection is indicated. The performance of proper TME was demonstrated by several independent groups to reduce local recurrence rates. This initiated the organization of master classes globally to teach colorectal surgeons the technique.

Technique

The patient is positioned in the extended Lloyd-Davis position. A urinary catheter is advised, as it drains the bladder and therefore reduces its size and consequently increases the operating field. It can also be used to monitor the urine output during the procedure.

A midline incision from the symphysis pubis towards the xiphisternum is made. In selected patients a lower midline incision can be performed instead. When the peritoneal cavity is accessed, it is important to ensure that the disease is still operable by looking for liver metastases, intra-abdominal dissemination, distant lymphadenopathy and fixation to nearby structures. The small bowel is then packed away into the right upper quadrant to optimize the operating field. A self-retaining retractor is used to keep it in place.

Mobilization of the descending (left) colon is traditionally performed from lateral to medial. The congenital adhesions between the sigmoid colon on the left lateral wall are divided with the use of coagulation diathermy exposing the peritoneal reflection. The peritoneal reflection is then incised to reveal the embryonic plane of dissection (white line), which must now be developed using countertraction and coagulation diathermy. Haemostasis is ensured with the use of monopolar or bipolar diathermy. When the sigmoid mesocolon is reached, the hypogastric nerves will be in view. The left ureter is identified and swept laterally to prevent any injury. The ureter is a whitish, non-pulsatile cord and shows peristaltic activity when gently pinched with forceps. The plane anterior to the hypogastric nerves is followed down into the pelvis until the plane between the mesorectum and the sacral fascia has been identified. The rest of the left colon is mobilized by extending the plane of dissection superiorly up to the splenic flexure.

Any obvious adhesions between the omentum and the splenic capsule are divided to prevent haemorrhage from tearing the splenic capsule when traction is placed on the omentum. This is only performed when the spleen is visible. Diathermy is used to divide the peritoneal connections between the lateral abdominal wall and splenic flexure. The plane between the omentum and the transverse mesocolon is identified and entered, by applying traction on the transverse colon and the attached greater omentum. This plane is developed and followed to the level of the splenic flexure providing adequate and quick mobilization of the splenic flexure.

With the division of the splenic flexure completed, the dissection of the peritoneum continues until the level of the aorta, where the origin of the inferior mesenteric artery can be found. It is dissected, ligated and divided. The inferior mesenteric vein is found superiorly at the inferior border of the pancreas and is also dissected and ligated close to its origin. This will complete the mobilization of the large bowel from the transverse colon to the distal sigmoid. Good perfusion is maintained up to the top of the rectum. This degree of mobilization will ensure that the anastomosis is tension free.

The colon is usually divided at the apex of the sigmoid colon (for low rectal cancers) unless this is significantly affected by diverticulosis, when a higher division at the descending colon may be more appropriate. The sigmoid mesentery is divided up to the colonic wall, including the ligated trunks of both the inferior mesenteric artery and vein. The proximal bowel is packed up into the left upper quadrant of the abdomen.

The application of forward traction to the rectum will reveal the plane between the mesorectum and sacral fascia with the hypogastric nerves lying on it. This is gradually developed using the coagulation diathermy, ensuring that the nerves are not injured and separated from the mesorectal surface. Preserving the nerves reduces the risk of damaging the parasympathetic nerves on the lower lateral wall of the pelvis and therefore the risk of impairing the bowel, sexual and urinary function. Dissection is then performed to the lateral sites of the rectum with the use of a curved St Mark's retractor and gentle countertraction of the rectum. When the planes are adequately dissected, anterior dissection commences.

This part is slightly different between the two genders. In females, the initial plane of dissection lies between the uterus and the mesorectum. Therefore, it may be useful to suture the uterus to the anterior abdominal wall. The division of the peritoneum is performed at the plane above and anterior to the apex of the rectovesical (males) or the rectouterine pouch (females). The anterior wall of the rectum is pulled posteriorly. The St Mark's retractor is positioned anteriorly to the rectum. In males, the plane continues between the anterior mesorectum and the seminal vesicles and in females between the anterior mesorectum and the vagina. With the completion of the anterior dissection, the posterior and lateral aspects are reviewed to ensure adequacy of the whole dissection. The lateral ligaments are not clamped, as this is likely to damage the parasympathetic plexus. The nerves from this plexus that supply the rectum are divided.

The pelvic floor should be reached. Lloyd-Davies scissors or vessel-sealing diathermy device can be used to divide any posterior strands. When the dissection is completed the lowest part of the rectum is viewed as a muscle tube. A linear stapler is positioned into the pelvis and the lowest part of the rectum is carefully placed into its jaws. This should be positioned low enough to achieve complete tumour resection, but high enough to allow a further line of staples to be placed below it. The rectal stump is then washed out with povidone iodine solution. The hypothesis is that it may kill any intraluminal tumour cells but the evidence is currently controversial.

The circular stapler is inserted through the anal canal and the centre rod is advanced through the centre of the staple line. It needs to be ensured that the colon is not twisted and that the head of the gun is attached to the centre rod. The staple gun is closed and fired. The anastomosis can be checked by direct palpation. A rigid sigmoidoscope is also used to insufflate air in the lower part of the rectum while the anastomosis is immersed in warm normal saline to ensure that there are no air leaks. A leak can be sealed with an extra suture and retested. The resected donuts are also checked and sent for histopathology examination to test for tumour at the margins. The anastomosis can also be hand-sewn. In the NHS, this is dictated by the surgeon's preference. Where cost is an issue, hand-sewn anastomosis is more cost-effective but increases the intraoperative time. There is no evidence to suggest a significant benefit in terms of anastomotic leak or recurrence rate.

In low rectal anastomosis a temporary loop ileostomy may be performed to protect the anastomosis until it is healed. Gastrografin enema is performed 6–8 weeks following the operation to assess the integrity of the anastomosis. Reversal of the anastomosis is performed 6–8 weeks following the primary operation or the completion of adjuvant chemotherapy. In addition some surgeons may perform a colopouch, aiming to improve bowel functione outcomes.

Sphincter preservation ultra-low anterior resection

In very low rectal cancers, an ultra-low anterior resection can be performed and therefore preserve the sphincter. A coloanal anastomosis can be performed to maintain bowel continuity. A temporary stoma is necessary to protect the anastomosis. It can be reversed at a later stage following complete recovery from surgery and completion of any adjuvant medical therapy that may have been given.

Technique

Following completion of TME as described above, the transanal part of the procedure can be performed. A hooked self-retaining retractor is used for better access and vision. A mixture of epinephrine (adrenaline) (1:100 000) is injected initially into the submucosal plane and higher up into the intersphincteric plane. An initial circumferential mucosectomy is performed from the dentate line. The distal part of the internal sphincter can be maintained depending on the tumour's proximity. It is important to completely resect the mucosa, as incomplete resection will compromise the anastomosis.

With the completion of mucosectomy the lower part of the rectum can be resected. The distal part of the remaining sigmoid or descending colon is brought to the anus, on top of the internal sphincter where an anastomosis will be performed. A tension-free anastomosis is essential and therefore complete mobilization of the splenic flexure is important. In order to protect the anastomosis, a defunctioning ileostomy or colostomy is performed. This can be reversed at a later stage following a water-soluble enema that shows no anastomotic leak.

Published results suggest that partial or complete excision of the IAS with a hand-sewn anastomosis can be performed with a low operative mortality (1.6%), and acceptable rates of anastomotic leakage (<10%) and local recurrence (9.5%). The potential disadvantage of performing a restorative operation for very low rectal cancers, particularly when all or part of the IAS is removed, is the unacceptable functional outcomes following the anastomosis. The extent of internal sphincter excision has been shown to influence the postoperative resting tone. Several strategies can be employed to improve the functional outcome by increasing the volume of the neorectal reservoir (such as the colonic J-pouch).

Extralevator abdominoperineal excision of rectum

Abdominoperineal excision of the rectum is performed for very low rectal cancers or locally advanced primary cancers that may be invading the ischiorectal fossa or posterior vaginal wall. The procedure is divided into two parts, the abdominal and perineal part. Following completion of the abdominal part, the surgeon will start the perineal dissection. The abdominal part is usually performed first as it will enable the assessment for distant metastases. Dissemination of the disease may result in the procedure being abandoned.

The perineal part of the procedure follows the completion of the abdominal part, which is similar to TME as described above (except when the tumour is locally advanced – extensive resection may be required). The anus is sutured closed with the use of a pearl suture. An oval incision around the anus is made. Its size depends on the tumour size and position.

Exposure is essential for the perineal part. The St Mark's retractor is commonly used to increase the view of the operative field. The dissection is progressed to the ischiorectal fossa on each side and then posteriorly towards the coccyx. Although the coccyx can be preserved unless the tumour extends posteriorly, the senior author's preference is to routinely excise this *en bloc* with the rectum as it reveals the posterior surface of Waldeyer's fascia, which is then excised together with the levator ani muscles. Co-operation between the abdominal and perineal surgeon is fundamental at this point as the abdominal surgeon guides the perineal surgeon as to where the dissection needs to be performed.

The abdomen is entered using scissors after the perineal surgeon identifies the lateral border of the levators with his index finger. The muscle is subsequently freed laterally from its pelvic attachments. Bilateral resection of the levators will free the rectum posteriorly and laterally. This will include both levators with the specimen (extralevator APER), minimizing the risk of incomplete resection and the risk of local recurrence. The prone position has been popularized in Europe for the perineal aspect of the dissection; however, the same procedure can be achieved by the modified Lloyd-Davis position.

Lateral pelvic sidewall lymphadenectomy (extended lymphadenectomy)

Technique

The current lateral lymph node dissection is performed the same way as Professor Moriya described it in 1989. Following dissection and mobilization of the sigmoid and descending colon, the pelvis is exposed enabling the initiation of the lateral dissection. The retroperitoneum is dissected at the level of the bifurcation of the aorta, exposing the common iliac vessels.

It is performed either *en bloc* with the internal iliac vessels or by preserving them, depending on the presence of tumour close to the internal iliac vessels or on the evidence of solitary lymph node metastases respectively. The lateral pelvic sidewall lymphadenectomy starts with the separation of the internal iliac vessels from the lateral ligament medially. All the branches of the internal iliac vessels are identified, ligated and divided as close to their root from the internal iliac vessels as possible.

For cases in which the tumour is close to the iliac vessels, the lateral pelvic sidewall lymphadenectomy is performed *en bloc* with the resected specimen, including the unilateral internal iliac vessels with preservation of the superior vesical artery and the obturator nerve. When the lateral pelvic sidewall lymphadenectomy is performed to remove lateral lymph nodes that are suspicious for malignancy, the nerve-preserving approach can be utilized. The specimen is resected *en bloc* with the tumour while the lateral pelvic sidewall spaces are opened between the lateral aspect of the internal iliac vessels and the pelvic sidewall, exposing the lateral lymphatic tissue and enabling harvesting of the lymph nodes. Using the nerve-preserving technique, the obturator nerve and internal iliac vessels with their branches are preserved without disturbing the sacral nerve plexuses.

With the completion of the lateral pelvic sidewall dissection and the abdominal mobilization of the specimen and depending on the tumour's extent, a TME or other more advanced operation can be performed (i.e. pelvic exenteration, posterior exenteration, abdominoperineal excision of the rectum or an abdominosacral resection).

Results

A meta-analysis compared the value of extended and non-extended lymphadenectomy of the lateral pelvic wall nodes in patients with primary rectal cancer and showed no overall difference in the oncological outcome. There was a marginal benefit for the extended lymphadenectomy group in survival and local recurrence, in patients with a Dukes' C but not Dukes' B carcinoma. However, the procedure increased the intraoperative time and blood loss by 76.7 minutes and 536.5 mL respectively. It was also associated with higher incidence of urinary and sexual dysfunction.

Management of advanced rectal cancer

When cancer has progressed to surrounding tissues and anatomical structures, the surgery required to achieve complete clearance is more complex with a higher risk of incomplete resection, morbidity and mortality. This group of patients should be managed at tertiary centres where expert specialists such as oncologists, radiologists, surgeons and histopathologists are present and are supported by appropriate infrastructure.

In an effort to establish criteria that would enable better prediction of tumour resectability and outcome, a number of classifications have been proposed. These are shown in Table 30.17.

All these classifications aim to describe to what tissue the tumour is fixed, and hence establish the potential for and extent of resection in order to define selection criteria for surgery along with prognostic information. The Royal Marsden classification has been found by the authors to be the most useful, enabling better communication and understanding between radiologists and clinicians. It helps to select patients for surgery and surgical planning and at the same time provides detailed information on the extent of the disease and signifies prognosis.

Selection criteria for surgery

The decision for surgery is made after extensive discussions at the local multidisciplinary meeting and relies heavily on the findings of the available diagnostic modalities. It is the radiological findings that will determine tumour resectability. Therefore, accurate preoperative staging can help to establish the extent of local disease and the presence or absence of distant metastases, which is imperative when considering patients for exenterative pelvic surgery for recurrent colorectal cancer.

Distant metastases

The presence of distant metastases is normally considered as a contraindication for exenterative surgery for locally advanced primary rectal cancer. It is generally contraindicated

Table 30.17 Staging classifications for locally advanced primary rectal cancer

Study group	Classificatio	Definition		Outcomes
Mayo Clinic	Symptoms	S0	Asymptomatic	Pain-free patients had better survival
		S1	Symptomatic without pain	
		S2	Symptomatic with pain	
	Degree and site of fixation	F0	No fixation	More points of fixation resulted in more complications and worse survival
		F1	Fixation to one point	
		F2	Fixation to two points	
		F3	Fixation to >2 points	
Yamada	Pattern of pelvic fixation	Localized	Invasion to adjacent pelvic organs or tissue	5-year survival of 38%
		Sacral invasive	Invasion to lower sacrum (S3, S4, S5), coccyx, periosteum	5-year survival of 10%
		Lateral invasive	Invasion to sciatic nerve, greater sciatic foramen, lateral pelvic wall, upper sacrum (S1, S2)	5-year survival of 0%
Wanebo	Five stages	TR1	Limited invasion of the muscularis	
		TR2	Full-thickness penetration of muscularis propria	
		TR3	Anastomotic recurrences with full-thickness penetration beyond the bowel wall and into the perirectal soft tissue	
		TR4	Invasion into adjacent organs without fixation	
		TR5	Invasion of the bony ligamentous pelvis including sacrum, low pelvic/sidewalls, or sacrotuberous/ischial ligaments	
MSK	Anatomical region involved	Axial	Anastomotic, mesorectal, perirectal soft tissue, perineum (APER)	Axial-only recurrence has 90% likelihood of R0; lateral recurrence is associated with 36% likelihood of R0
		Anterior	Genitourinary tract	
		Posterior	Sacrum and presacral fascia	
		Lateral	Soft tissues of the pelvic sidewall and lateral bony pelvis	
Royal Marsden	MRI; planes of dissection	Central	Rectum or neo-rectum, intraluminal recurrence, perirectal fat or mesorectum, extraluminal recurrence	MRI diagnosis of tumour invasion within the lateral, posterior or in more than two compartments was associated with reduced disease-free survival
		PR	Rectovesical pouch or rectouterine pouch of Douglas	
		AA PR	Ureters and iliac vessels above the peritoneal reflection, sigmoid colon, small bowel and lateral sidewall fascia	
		AB PR	Genitourinary system	
		Lateral	Ureters, external and internal iliac vessels, lateral pelvic lymph nodes, sciatic nerve, sciatic notch, S1 and S2 nerve roots, piriformis or obturator internus muscle	
		Posterior	Coccyx, presacral fascia, retrosacral space, sacrum up to the upper level of S1	
		Inferior	Levator ani muscles, external sphincter complex, perineal scar (APER), ischioanal fossa	

AA, anterior above; AB, anterior below; APER, abdominoperineal excision of the rectum; PR, peritoneal reflection

due to the significant morbidity that is associated with this type of procedure. It has been demonstrated by some centres that synchronous or staged resection of metastases can have acceptable results in highly selected patients.

Resectable cancer

In the absence of distant disease, surgical resection of the advanced primary cancer is the only potentially curative option. Surgery for advanced primary rectal cancer includes a range of different procedures that depend on the extent of the disease and the specific organs/structures that are involved. Surgery is performed *en bloc* and is considered curative when the resection margins are free of microscopic disease (R0 resection). Microscopic or macroscopic residual disease at the resection margins are defined as R1 and R2 resection respectively.

Contraindications for surgical resection

It is essential to assess the patient's fitness for surgery before discussing surgery with the patient, since lack of fitness could be a contraindication when undergoing such a major procedure.

Surgery is contraindicated in the presence of:

- circumferential or extensive lateral pelvic sidewall involvement
- involvement of the iliac vessels
- bilateral ureteric obstruction
- sciatic nerve involvement
- para-aortic lymph node metastases
- irresectable distant metastases.

Limited tumour invasion to the lateral pelvic wall and invasion of the sacrum above the S2 vertebrae are considered relative contraindications since there are surgical options in both cases, but the likelihood of a complete resection is considerably lower.

Irresectable local cancer

Surgical resection and chemoradiotherapy can be used for palliation alleviating the patient's symptoms that are related to the organs/structure which have been invaded by tumour. It has been suggested that palliative resection can improve quality of life and pain relief. However, it is usually unsuitable because of the high morbidity rate related to this type of surgery. It is therefore important that patients are carefully selected for palliative procedures, taking into consideration possible comorbidities and their social circumstances, as the benefits from these procedures are short term.

Surgery for metastatic disease

It is now recognized that a proportion of patients with hepatic metastases from colonic cancer are suitable for liver resection. Approximately 10% of all patients with colorectal cancer are found to have synchronous liver metastases and half of these (5% of the total) have resectable lesions. A further 10% of patients will develop metachronous liver metastases within about 2–3 years of resection of the primary colorectal cancer. The important criteria for resectability of hepatic metastases from large bowel cancer are as follows.

- The primary tumour must be controlled with no evidence of extrahepatic metastases.
- All of the hepatic metastases must be resectable with an adequate margin of at least 2 cm of normal liver tissue.
- The operation must be performed with an acceptable mortality and morbidity.

Although the best results are associated with solitary metastatic lesions, it is possible to carry out extensive liver resections for multiple disease. Analysis of several large series indicates that multiple factors influence survival after hepatic resection. These are as follows.

- *Stage of the primary tumour.* The more advanced the stage of the primary lesion the worse the prognosis after liver resection.
- *Number of metastases and their location within the liver.* Patients with more than three metastatic lesions and those with bilobar disease tend to fare badly.
- *The interval of time between resection of the primary lesion and the appearance of the hepatic metastases.* The longer the period the better the prognosis.
- *Sex of the patient.* In general, women live longer than men after resection of liver metastases.
- *The presence of extrahepatic metastases.* This adversely influences the results of liver resection.
- *The operative mortality.* Modern surgical standards dictate that this should be under 5% even for a major lobectomy or extended right hepatectomy.

Although there has been no randomized trial there is little doubt that resection of liver metastases confers a survival advantage. With careful patient selection, hepatectomy for colorectal metastases is associated with a 5 year survival around 30%, which is the same prognosis as is associated with resection of a stage C cancer without evidence of distant metastases.

In patients with liver metastases which are not suitable for liver resection, then *in situ* ablation using cryotherapy or radiofrequency probes may be of value. Currently this is performed under ultrasound control, either at open surgery or laparoscopically. It seems to be associated with a modest prolongation of survival. Future developments include percutaneous *in situ* ablation using MRI-guided probes in an open magnet and the use of extracorporeal high-energy focused ultrasound to destroy tumour deposits (see also Chapter 24).

Laparoscopic vs open surgery

Laparoscopic colorectal surgery has evolved immensely during the recent years. Colorectal surgeon training is more specialized and there is focus in the use of laparoscopic surgery. There has been extensive interest in the application of laparoscopic surgery in colorectal cancer, with a significant number of publications investigating the short- and long-term benefits. The mean operative time is significantly longer when laparoscopic surgery is performed. Laparoscopic surgery is associated with less pain (and analgesia requirements), faster recovery of intestinal motility and return to normal diet, and significantly lower overall morbidity. These factors contribute to a shorter hospital stay. With the introduction of enhanced recovery protocols, however, these effects may be less significant.

Worldwide there is now a substantial published experience of laparoscopic surgery for colonic cancer, and the early concerns regarding laparoscopic surgery for colonic cancer have been dismissed by the results of several randomized controlled trials which have confirmed identical oncological outcomes and survival rates together with benefits in terms of reduced blood loss, less postoperative pain and faster recovery of gastrointestinal function.

These randomized controlled trials, meta-analyses and systemic reviews have confirmed no difference in the reported disease-free survival between laparoscopic and open surgery. In trials reporting on tumour recurrence, two randomized controlled trials reported zero event rates in both surgery groups. Worldwide, there have been only three reported instances of port site deposits. Four studies were included in a meta-analysis on hazard ratios for tumour recurrence in laparoscopic colorectal cancer surgery. No significant difference in recurrence rate was observed between laparoscopic and open surgery. Likewise, no significant difference in tumour recurrence between laparoscopic and open surgery for colon cancer was observed between the two groups. In a Cochrane review, 33 randomized clinical trials comparing laparoscopically assisted vs open surgery for colorectal cancer were identified. Twelve of these randomized controlled trials involving 3346 patients reported long-term outcome and were included in the analysis. No significant differences in the occurrence of incisional hernia, reoperations for incisional hernia or reoperations for adhesions were found between laparoscopically assisted and open surgery. Local recurrence rates at the site of the primary tumour were similar (5.2% vs 5.6%). The review identified four randomized controlled trials for rectal cancer (714 patients) and found similar local recurrence rates (7.2% vs 7.7%). There were no differences in the occurrence of port site/wound recurrences. This review also reported similar cancer-related mortality for colon cancer

(1575 patients, 14.6% vs 16.4%) and for rectal cancer (578 patients, 9.2% vs 10.0%).

In the UK, NICE now supports and advocates the laparoscopic approach, provided the surgeon is fully trained. The decision about whether to use open or laparoscopic surgery should be made after informed discussion between the patient and the surgeon, taking into consideration the patient's condition and suitability for laparoscopic surgery, the risks and benefits of the two approaches, and the surgeon's experience in laparoscopic colorectal surgery. Although reported for all ages, the benefits of laparoscopic colorectal cancer are especially marked in elderly patients.

Postoperative outcomes

Approximately 40% of patients with colorectal cancer will die from the disease within 5 years of surgery. Eighty per cent of recurrences are seen during the first 2 years after primary tumour resection, thus there has been discussion to suggest the intensity of the follow-up regimen should be highest in the first few years.

The aims of follow-up for colorectal cancer include:

- management of postoperative complications
- early detection of recurrence, either local or distant
- early detection of new primary tumour
- aids decision-making for possible adjuvant therapies
- audit of outcomes
- assess quality of life
- patient reassurance.

Most studies that have compared aggressive follow-up with less aggressive strategies have suggested that increased surveillance has a positive trend with survival advantage. This may be due to earlier discovery of treatable recurrences amenable to curative reresection. However, there is meta-analytical work that has suggested that although intense follow-up may pick up some asymptomatic recurrences, the numbers needed to treat are very high and this leads to high labour intensity and poor cost effectiveness. The same work suggested that the focus of colorectal cancer follow-up should shift from the early detection of recurrence towards quality of life assessment and patient support.

Patient follow-up involves clinical review, serum tumour markers, endoscopy and radiology.

Clinical review

Several randomized studies have shown possible benefits but because of relatively small sample sizes the results were not statistically significant. However, a meta-analysis showed that more intensive follow-up leads to an increase in 5 year survival advantage. A previous meta-analysis was unable to show any significant increase in 5 year survival rate for intensive follow-up of patients with colorectal cancer operated on for cure, but this study did not include the use of CEA for early detection of recurrence and also included data from two non-randomized trials as part of the results.

Likewise, in the single-cohort studies, those patients with intensive follow-up were almost twice as likely to have a curative resection for recurrence than patients in the historic control group, thus strongly advocating the benefit of a more intense follow-up strategy, which also allows a higher chance of picking up recurrence in those patients at higher risk.

However, as already discussed above, others advocate less intense follow-up, stating that the numbers needed to treat are far too high and that there is no adequate curative treatment for most recurrences anyway, especially if TME was performed correctly in the first instance. There is also new discussion as to who should be carrying out the follow-up process. Advocates of intense follow-up recommend surgical teams, and this seems logical in the immediate and short-term postoperative period. But in the long term there are questions of which healthcare provider should be the key contact. Should there be more primary care involvement for example? Which clinicians would provide quicker diagnosis of recurrence but also have a more positive effect on the quality of life of the patients? Such questions are indeed contentious; however, currently each patient situation should be considered individually as there is no real hard evidence to answer the above questions.

Prognosis

Studies such as Eurocare-3 have clearly shown how survival from colorectal cancer in the UK differs from other European countries, with overall 5 year survival being 45.1% for men and 49.6% for women.

Blood tests: serum tumour markers

CEA has been used extensively both in the USA and in Europe for follow-up for many years now, with the prospect that it is able to detect recurrence possibly up to 6 months prior to symptoms. There is evidence that this relatively simple test leads to earlier diagnosis and more reoperative management. But does this mean more cure for recurrence? This is unlikely, and there is little evidence to suggest that second-look surgery changes survival rates on the whole. It has been demonstrated in the literature that at times there may be hundreds of thousands of patients undergoing serial CEA measurements, and this undoubtedly has cost implications. The same study showed less than excellent sensitivities and specificities for CEA levels and recurrence and led the investigators to conclude that cancer cures attributable to CEA monitoring are, at best, infrequent. It is still questioned whether this small gain justifies the substantial financial cost and physical and emotional stress that this intervention may cause for patients.

However, a Dutch meta-analysis published more recently suggests the CEA should in fact be used primarily for the early diagnosis of recurrence. But this study also suggests that the numbers needed to treat are high, and so still may not be cost effective. These contentious issues may be resolved when the results of the St Marks randomized trial on CEA levels during follow-up are published.

Other markers have been studied, e.g. CA 19-9 (carbohydrate antigen) and TPA (tissue polypeptide) and compared with CEA, but CEA seems to be the most sensitive and combinations of measured markers do not seem to change overall sensitivity and specificity.

Flexible endoscopy/colonoscopy

Endoscopy is often performed at 1, 3 and 5 years following resectional surgery and has two important roles:

- recognition of recurrence
- detection of metachronous tumours.

It must be remembered that endoscopic techniques are relatively insensitive for detecting recurrences, but this is because half of all recurrences do not originate from within the bowel lumen. Thus its main use is that of diagnosing new primary neoplastic lesions. Guidelines set forth by the American Society of Colon and Rectal Surgeons recommend surveillance colonoscopy 1 year postoperatively, then every 3 years if the colon is normal, which implies annual examinations until a normal examination is obtained.

The data from a study reported the findings of annual surveillance colonoscopy in colorectal cancer patients, and concluded the following.

- The risk for a positive initial postoperative colonoscopy was 18.3%.
- After a normal colonoscopy, risk for finding a neoplastic polyp on the next annual examination was 10.4%.
- After a positive colonoscopy, risk for finding a neoplastic polyp on the next annual examination was 43%.
- The risk for a positive examination after finding multiple neoplastic polyps was 70.4%.

The investigators concluded that annual follow-up colonoscopy for 2 years after colorectal cancer surgery is beneficial for detecting recurrent and metachronous neoplasms and that the interval between subsequent examinations may be increased depending on the result of the most recent examination.

Imaging

Ultrasonography has long been used to image the liver accurately with regards to metastases. Generally it is sensitive and specific for even small lesions (e.g. 1 cm in diameter), although it is highly operator dependent.

Besides imaging the liver, ultrasound scanning has also been used to assess local recurrence of rectal cancer using endoluminal ultrasound techniques. A study showed the sensitivity of endoluminal ultrasound and CT for recurrence to be 100% and 86% respectively with a specificity of 89% and 93% respectively. Overall, the accuracy for both imaging techniques was found to be 93% and 83% respectively. However, because of small study size the findings were not statistically significant.

CT has long been considered to be effective in the diagnosis of colorectal cancer recurrence but with varying sensitivities. It undoubtedly, along with MRI, is excellent at delineating recurrence in the surrounding pelvic cavity. In many centres it is the diagnostic tool of choice. But its limitations must be remembered:

- lesion diameter
- low sensitivity for lymph node recurrence
- artefacts from surgical clips
- difficulty in differentiating between postoperative scarring and recurrence.

MRI has proved to be superior to CT tissue characterization even in the presence of surgical artefact enabling just as high, if not higher, sensitivities and specificities compared with CT. However, availability, cost and patient factors (e.g. metal prosthesis, claustrophobia) make this investigation less usable on occasion. MRI may also be used endoluminally and this may yet yield better results, possibly because of its deeper focal length.

One of the difficulties of both CT and MRI is differentiating between recurrence and scar tissue; however, this issue may be improved by the use of serial scanning rather than just one-off imaging. PET may also be used in allowing differentiation of recurrence from surgical change.

Screening for colorectal cancer

It is well established that 'early' colorectal tumours (i.e. stage A) have a much better prognosis than more advanced tumours, and it therefore makes sense to try to diagnose colorectal cancer at an early stage. Unfortunately, the common symptoms of colorectal cancer (i.e. change of bowel habit, abdominal pain and rectal bleeding) only occur when the tumour is relatively locally advanced. The only way in which to reliably identify cancers at an early stage is to employ population screening, and a great deal of research effort has gone into this approach over the past 20 years.

There are now three population-based randomized controlled trials which have demonstrated that screening asymptomatic populations with faecal occult blood testing can reduce disease-specific mortality by 15–30%. Unfortunately, standard faecal occult blood testing, which is positive in about 2% of an unselected population between the ages of 50 and 75 years, is only about 50% sensitive. Thus a negative faecal occult blood test is not a guarantee that colorectal cancer is not present, although a positive test is associated with a 50% chance of colorectal neoplasia and a 12% chance of having invasive malignancy. It is possible to increase the sensitivity of faecal occult blood testing, but this reduces the specificity to such an extent that a large number of negative investigations would have to be carried out.

Another approach to screening is to use flexible endoscopy as the primary screening test. To use colonoscopy in this way would be impractical, but flexible sigmoidoscopy is a more realistic proposition. As 75% of colorectal cancers are within the reach of this instrument and as the presence of an adenomatous polyp in the left colon is an indicator of possible neoplasia on the right of the colon, then a 'once-only' flexible sigmoidoscopy may be a useful screening test. This is the subject of a randomized trial carried out in the UK, but mortality data from this trial are not yet available. One of the problems with all forms of colorectal cancer screening is the low compliance rate, which is presumably related to a mixture of ignorance, fear and distaste.

Large bowel polyps

Polyps

The term polyp is rather imprecise and in its broadest sense can be taken to mean a protuberant growth which can be either benign or malignant. As far as the colon and rectum are concerned, however, the term is usually taken to mean a benign swelling arising from the colonic or rectal mucosa, although, as it will be seen later on, certain types of polyp may contain a malignant or invasive focus and may indeed be an essential precursor in the development of colorectal cancer. Colorectal polyps may be inflammatory, hamartomatous, metaplastic or adenomatous. These will be dealt with in turn, but particular attention will be paid to the adenomatous variety in view of their close association with colorectal cancer.

Inflammatory polyps

These occur in ulcerative colitis, Crohn's colitis, diverticulitis, chronic dysentery and in benign lymphomatous lesions of the colon. They are sometimes referred to as pseudopolyps as they are commonly formed from an island of hypertrophied mucosa in an area of inflammation and ulceration. These polyps tend to be small, rarely exceeding 0.5 mm in diameter and consist of inflamed congested mucosa with oedematous changes in the submucosa.

Hamartomatous polyps

Hamartomatous polyps may be found in two forms, as juvenile polyps and as the familial Peutz–Jeghers syndrome. Juvenile polyps are found in infants or children and are often multiple, being round or oval with a smooth surface. At the time of diagnosis most lesions are pedunculated with a transition from normal colonic mucosa to a type of glandular tissue at the junction of the stalk and the polyp. The polypoidal substance consists of vascular tissue infiltrated by inflammatory cells and contains cystic spaces maintained by mucus-secreting columnar cells. There is a familial tendency in juvenile polyposis with the majority of patients presenting before the age of 10 years. Male children predominate over female. Fortunately, they are single in 70%, and 70% occur in the rectum and distal sigmoid colon.

The polyps occurring in the Peutz–Jeghers syndrome are associated with pigmented lesions (a bluish brown discoloration) on the face and on the lingual and buccal mucosa. Here the familial tendency is very strong. The polyps are almost always multiple and are found more commonly in the small bowel than in the colon or rectum. On histological examination the basic malformation is found in the muscularis mucosae. Unlike juvenile polyposis there is a significant malignant potential and there are reports of carcinoma arising in young patients with this syndrome (see also Chapter 29).

Metaplastic polyps

These are generally plaque-like growths which vary in size from 1 to 2 mm but rarely exceed 5 mm in maximum diameter. Although they are most commonly found in the rectum, the whole of the large bowel is susceptible. There is no specific age distribution or predisposing factor. On histological examination there is lengthening of the mucosal glands with dilatation of the goblet cells and evidence of inflammatory infiltration of the lamina propria. It is not understood why these lesions arise but they are very rarely symptomatic and do not appear to be premalignant. There is however some evidence that the presence of metaplastic polyps in the rectum or distal colon may be associated with an increased risk of adenomatous polyps or even carcinoma in the more proximal colon.

Adenomatous polyps

Pathology

Adenomatous polyps are benign neoplastic growths arising from the mucosa of the intestine and although they may occur anywhere between the stomach and the rectum, they are most common in the large intestine. In the Western world they are extremely common and postmortem studies indicate that they are found in more than 30% of people over the age of 60 years. The distribution of polyps is similar to that of adenocarcinoma, i.e. commonest in the rectum and left side of the colon, rare in the transverse colon and with a slight increase in the incidence in the right side of the colon and caecum. Adenomas are highly variable in size and macroscopically may be pedunculated or sessile. Recently the concept of the flat adenoma, which can be defined as an area of adenomatous change barely discernible macroscopically has emerged, but the significance of these lesions has yet to be established. In the colon, adenomas are normally pedunculated whereas in the rectum they are commonly sessile. The villous papilloma is a sessile adenoma made up of frond-like strands which grows as a carpet on the rectal mucosa (Figure 30.50).

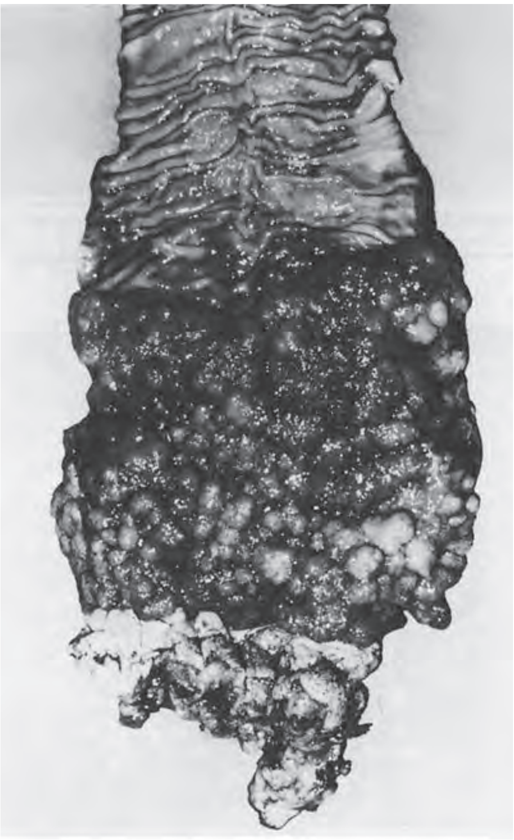

Figure 30.50 Extensive villous adenoma of the rectum.

Histologically, the epithelium in an adenoma can be arranged in tubular pattern consisting of closely packed glands or a villous pattern where the epithelial cells are arranged on frond-like extensions from the surface of the tumour. In practice the majority of adenomatous polyps display a mixture of tubular and villous patterns and can be described as tubulovillous. When the pathologist examines an adenoma it is important to establish whether or not there are any areas of invasion where dysplastic cells have transgressed the basement membrane into the fibrous stalk of the polyp. This will be found in about 50% of all adenomas that are over 2 cm in maximum diameter. In general, villous adenomas are more likely to undergo malignant change than tubular adenomas but this is by no means an absolute rule.

Aetiology

The aetiology of adenomatous polyps is essentially the same as that of colorectal cancer, indeed it is believed that the majority of colorectal cancers arise from pre-existing adenomatous polyps (see next section). In summary, although environmental factors (probably mainly dietary) have important implications for the formation of polyps, the genetic background is crucial. Not only are there dominantly inherited mutations which predispose to the development of polyps and cancer (see sections Familial adenomatous polyposis and Hereditary non-polyposis colorectal cancer) but there are also more subtle genetic variations which have an important impact on the predisposition to develop adenomatous polyps. This will be dealt with in detail in the section Colorectal cancer.

Clinical features

Most adenomatous polyps are asymptomatic and the diagnosis is made on routine examination. Nevertheless, both occult and frank bleeding can occur and patients may present with either rectal bleeding or anaemia. Occasionally, polyps may be extruded from the anal canal and may be misdiagnosed as prolapsing haemorrhoids. The retrograde propulsion of larger pedunculated polyps may produce abdominal pain and in extreme cases lead to the development of colocolic intussusception.

Rectal polyps may be accompanied by tenesmus and a change in bowel habit to diarrhoea. This may be the result of mucoid discharge from the surface of the polyps. This feature is particularly common with villous papillomas where spurious diarrhoea from the abundant mucus discharge leads to a failure in health, dehydration and electrolyte disturbance. In the mucus, sodium and chloride concentrations are similar to plasma but the potassium concentrations are between three and 20 times greater. Thus in larger papillomas, hypokalaemia and metabolic acidosis may result in lethargy, muscle weakness, mental confusion and in some extreme cases renal failure. These metabolic disturbances require attention prior to any attempt at surgical treatment.

Diagnosis

The diagnosis of adenomatous polyps is made on either large bowel endoscopy or barium enema. Large bowel endoscopy (colonoscopy in particular) is more sensitive at identifying polyps but large polyps can easily be seen on a high-quality, double-contrast barium enema (Figure 30.51). In some instances, it may be difficult to distinguish among a polyp, a diverticulum and faecal material, and this gives rise to a significant false-positive rate of polyp detection using barium enema. It must also be stressed, however, that colonoscopy is not 100% sensitive either and it has been demonstrated that repeat colonoscopy can often demonstrate lesions which were missed on the previous colonoscopy and miss lesions which had already been seen. One advantage of endoscopic diagnosis of polyps is that a biopsy can be taken of the larger polyps. This is important as it is often difficult to distinguish between a large benign adenomatous polyp and a polypoid carcinoma. Colonoscopy also offers the opportunity to remove the polyp using snare diathermy (Figure 30.52).

Prognosis

The prognosis of benign polyps in themselves is usually good, with the proviso that large villous adenomas can be extremely

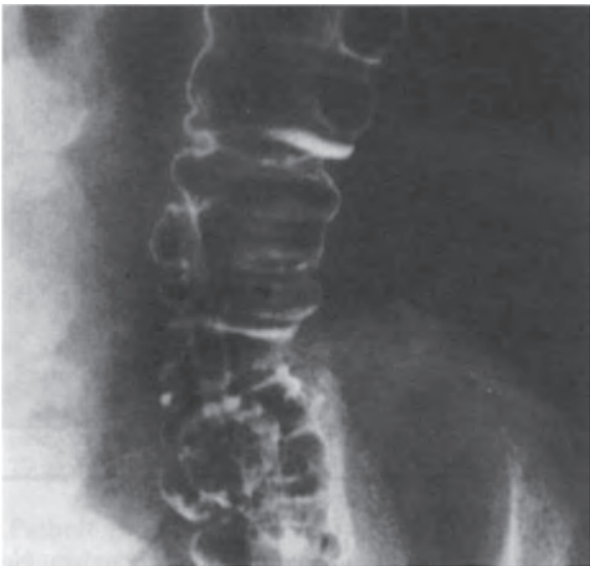

Figure 30.51 A 2.0 cm polyp on a stalk demonstrated by double-contrast barium enema.

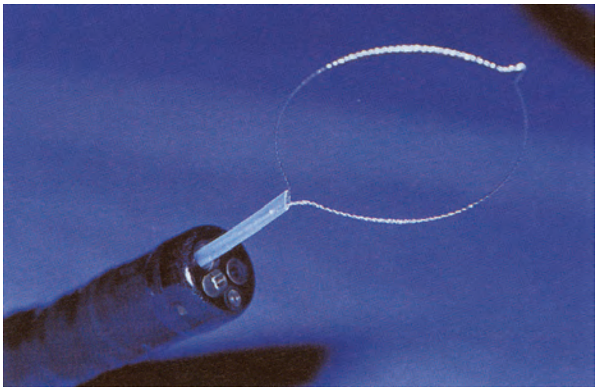

Figure 30.52 Colonoscopic snare.

debilitating (see above). However, as most carcinomas are thought to arise from polyps, the potential for malignant change should never be ignored and wherever it is feasible benign adenomatous polyps should be removed.

Treatment

The mainstay of treatment of adenomatous polyps is endoscopic polypectomy. Using a colonoscope, a wire loop is placed around the stalk of a pedunculated polyp; a blended current is then passed along the snare which is gradually tightened until it cuts through the stalk (Figure 30.53). The polyp should then be retrieved for histological examination. Occasionally, polypectomy may be accompanied by brisk arterial bleeding. If this occurs, the endoscopist should grasp the bleeding stalk with the snare, tighten the snare and hold in place for about 5 minutes without using diathermy current. This will usually stop the bleeding.

Another important complication of polypectomy is perforation of the colon. All patients undergoing colonoscopy with polypectomy should be warned of the risks of bleeding and perforation, as both may require emergency surgery. When a colonic polyp is sessile or has a very broad stalk, then it may be hazardous to carry out a standard polypectomy owing to the risk of perforation. In this case it is possible to elevate the polyp by injecting saline into the submucosa (Figure 30.54). This will allow much safer polypectomy. In very large polyps, it may be possible to carry out piecemeal snare excision. This is a difficult and hazardous procedure and should only be carried out by experienced endoscopists.

When a polyp has been completely excised and sent for histology, a focus of invasion will occasionally be found within the polyp making it a polyp cancer. It is generally agreed that if the polyp has been removed in one piece and the invasion does not extend to the resection margin then further surgery is not required. However, if the resection margin is involved, the patient should then be offered a colectomy. For this reason, if an endoscopist is concerned that a polyp may in fact be a cancer, it is useful to mark the site of excision using an intramural injection of India ink via the colonoscope. Having said this, many surgeons will take the view that a large polyp in the colon is highly likely to be malignant, even in the absence of confirmatory biopsies and will advise the patient to go straight to colectomy.

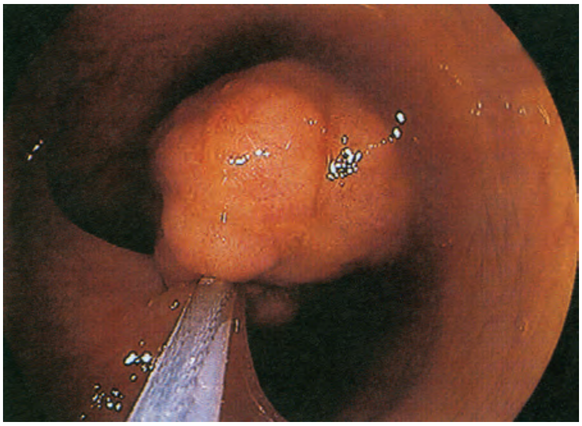

Figure 30.53 Snare excision of a polyp.

Although these endoscopic approaches are suitable for the majority of colonic polyps, rectal polyps pose a different problem. Occasionally, a large pedunculated prolapsing rectal polyp can be pulled out through the anal canal and the stalk simply ligated and divided. However, the majority of rectal polyps are sessile and require a different approach. Traditionally a low sessile rectal polyp was treated by submucosal saline injection to lift it away from the muscle wall and then transanal excision using Park's anal retractors to gain access (Figure 30.55).

For polyps which are higher in the rectum, however, this is often not feasible, and for this reason TEMS was developed. This employs a sophisticated operating sigmoidoscope with

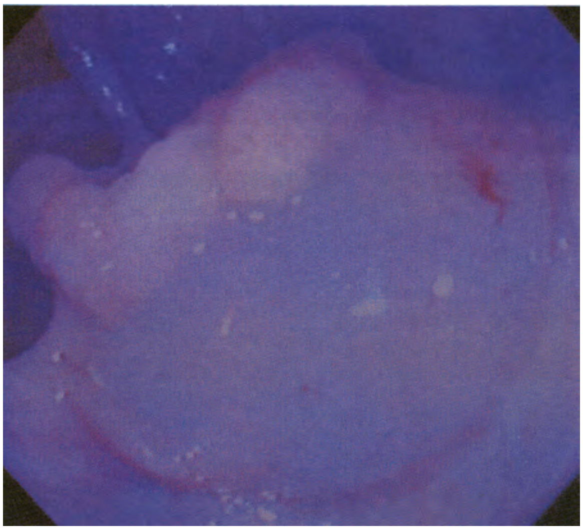

Figure 30.54 Elevation of polyp after submucosal saline injection.

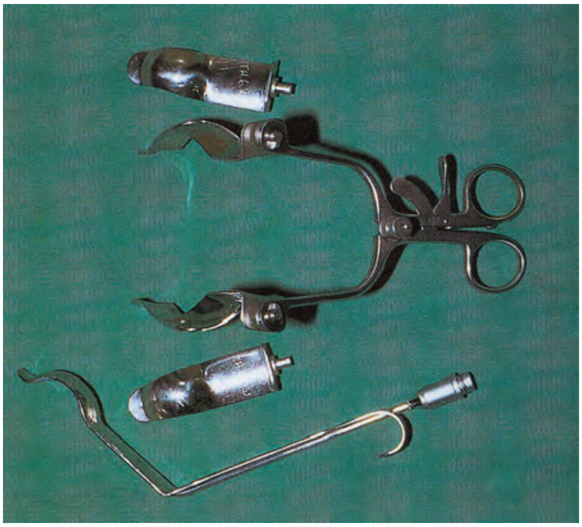

Figure 30.55 Parks' anal retractor for local transanal excision of rectal tumours.

a binocular optical system (Figure 30.48), which, by means of continuous insufflation and suction, offers an excellent operating environment to remove such polyps. When these polyps are situated posteriorly, it is safe to remove a full-thickness disc of rectal wall and this is a sensible precaution as a proportion of such polyps will harbour invasive malignancy. However, anteriorly above about 10 cm this is hazardous as it may lead to perforation into the peritoneal cavity and a submucosal technique must be employed. An alternative procedure is the trans-sphincteric approach described by Yorke Mason, which involves formal division of the anal sphincter mechanism in order to gain access to the rectum posteriorly. Owing to the currently available sophisticated techniques for transanal excision, however, this approach is seldom used nowadays. Occasionally, a patient will have such an extensive carpet of adenoma throughout the rectum that a transanal approach is not feasible. In this case a total proctectomy (i.e. an anterior resection with a mucosectomy down to the dentate line) has to be carried out. Continuity can then be restored by means of a sutured coloanal anastomosis.

Familial adenomatous polyposis

FAP is a dominantly inherited condition characterized by the appearance of multiple adenomatous polyps throughout the colon, which inevitably lead to colorectal cancer by the fourth decade of life. It is caused by a germline mutation of the *APC* gene, which is located on chromosome 5q and functions as a tumour suppressor gene with implications for cell-to-cell adhesion. The severity of the polyposis is variable and is related to the specific mutation, e.g. mutations at codon 1309 (exon 15) are associated with a very dense polyposis.

Although colonic polyps are the most important phenotypic manifestation of this condition, there are also extracolonic features which appear to a varying degree. These include adenomas and carcinomas of the small bowel and particularly the periampullary area of the duodenum, congenital hypertrophy of the retinal pigment epithelium (CHRPE) (Figure 30.56) and desmoid tumours. When FAP occurs in association with desmoid tumours, epidermoid cysts and bony exostoses, it is termed Gardener syndrome and this appears to occur in about 10% of cases.

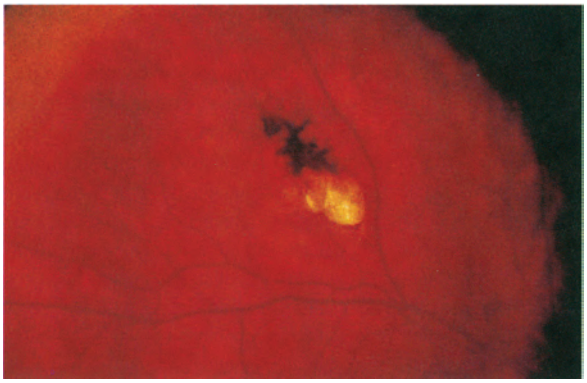

Figure 30.56 Congenital hypertrophy of the retinal pigment epithelium.

Clinical features

Commonly this condition is picked up by surveillance, as children of affected individuals have a one in two chance of developing colonic polyps. However, in an individual not suspected of having FAP, the most usual presenting symptom is rectal bleeding. CHRPEs may be seen on retinoscopy and desmoid tumours usually present as abdominal wall or intra-abdominal masses.

Diagnosis

The age at which the polyps develop is variable, but it is usually in the late teenage years and early twenties. For this reason, individuals at risk of FAP should undergo yearly sigmoidoscopy from puberty onwards. Genetic screening is now possible, and once the specific mutation in the *APC* gene has been detected by genetic sequencing in an affected individual, his or her children can then be screened for that specific mutation. If they do not carry the mutation, then endoscopic surveillance will not be necessary.

Treatment

The treatment for FAP is colectomy soon after the development of the adenomatous polyps (usually in the early twenties). There is some debate whether a total colectomy with ileostomy or ileoanal pouch should be performed or whether it is safe to carry out a subtotal colectomy with ileorectal anastomosis followed by careful follow-up of the rectum with ablation of the polyps when they arise. Mutation analysis may help in this respect and it might be reasonable to plan the operation depending on the likely density of polyps (i.e. those with the mutation at codon 1309 at exon 5 might be best served by a total proctocolectomy, whereas in other mutations an ileorectal anastomosis may be appropriate). More work is required in this area.

Hereditary non-polyposis colorectal cancer

While FAP probably accounts for 1–3% of all colorectal cancers, HNPCC may account for 5–10%. Like FAP, HNPCC is a dominantly inherited condition, but as it does not lead to multiple polyposis it is more difficult to recognize. The germline mutations which lead to HNPCC are thought to occur in DNA mismatch repair genes and currently four are recognized – *hMSH2*, *hMLHl*, *hPMSl* and *hPMS2* – but 90% of mutations in HNPCC are found in *hMSH2* and *hMLHl*.

Clinically, the diagnosis of HNPCC depends on the 'Amsterdam criteria', which require three or more relatives with histologically verified colorectal cancer, one of whom is a first-degree relative of the other two, with at least one patient being less than 50 years of age. HNPCC is associated with an excess risk of extracolonic cancers and is classified into 'Lynch' syndromes 1 and 2 on the basis of extracolonic disease. In Lynch syndrome 2, there is a particularly strong association with endometrial and ovarian cancer but other malignancies which may occur include transitional cell carcinoma of the ureter and renal pelvis, gastric cancer, pancreatic cancer, biliary tract cancer and haematological cancers.

Clinical features

Clinical features are merely those of the cancer that develops, particularly colorectal cancer. It should be stressed that multiple polyps do not occur, although small numbers of adenomatous polyps are a feature of this condition. The lifetime risk for colorectal cancer is about 85% of affected individuals, which indicates incomplete penetrance of this inherited condition.

Diagnosis

In individuals at risk the current recommendations are that colonoscopy should be performed at the age of 25 years, then repeated every second year until the age of 35 and then repeated yearly. The reason for the increased frequency at 35 years is that the average age of developing colorectal cancer is around 40. Women with Lynch 2 syndrome may also be offered screening of the endometrium by endometrial aspiration and yearly measurement of the CA 125 tumour marker. It is now possible to carry out mutation analysis for the known mismatch repair gene mutations. Once a specific mutation is known in an affected individual, their offspring may be offered genetic screening.

Treatment

When a cancer has been identified it is usual to offer a subtotal colectomy and ileorectal anastomosis in view of the high risk of metachronous tumours. Whether or not prophylactic colectomy should be carried out in subjects known to be carrying a germline mutation in one of the appropriate genes is controversial but has its supporters. The main argument against this approach is the fact that the condition is not fully penetrant.

Unusual colorectal cancers

Squamous cell carcinoma

Squamous cell carcinoma of the colon or rectum is extremely rare and may be related to squamous metaplasia of existing adenomas or carcinomas. Chronic ulcerative colitis, schistosomiasis and radiotherapy are all other possible predisposing factors. This type of cancer presents as ordinary adenocarcinoma and the diagnosis is only made on histology. Squamous carcinoma of the colon and rectum must be differentiated from anal carcinoma which is a distinct clinical entity.

Carcinoid tumours

The most common site for carcinoid tumours is the appendix followed by the small intestine. The large bowel is the third most common site, with the rectum or anus being the most frequent. The tumours are usually polypoid in nature and appear to be slow growing, remaining asymptomatic for long periods of time. Indeed about 50% of patients with colonic carcinoids have no symptoms attributable to the primary tumour at the time of diagnosis. Carcinoids are dealt with in more detail in Chapter 29.

Lymphoma

Malignant lymphoma is the third most common malignant tumour of the large bowel after adenocarcinoma and carcinoid tumours but probably represents only about 1.5% of all colonic tumours. The commonest sites are the rectum and the caecum. The tumours are usually of the non-Hodgkin's variety. Because these tumours are rare, definitive guidelines on treatment are difficult to provide. However, it is generally recommended that colonic tumours should be treated by chemotherapy alone, whereas rectal tumours should be treated by a combination of radiotherapy and chemotherapy. Surgical resection should follow unless there is a complete response to non-surgical therapy.

Sarcoma

Various types of sarcoma can arise in the colon and rectum and present in very much the same way as adenocarcinoma. Of particular note in recent years is Kaposi's sarcoma which is a feature of HIV infection. This tumour has been reported as being the presenting feature in AIDS in about 25% of cases and is manifested by multiple lesions in the gastrointestinal tract and the skin. The rectum is a common site and this leads to symptoms suggestive of IBD (diarrhoea and ulceration). Radiotherapy and chemotherapy may be used to treat Kaposi's sarcoma and occasionally surgery is required.

Vascular disorders of the colon

Vascular disorders of the colon can be classified into three main categories:

- ischaemic colitis
- angiodysplasia
- visceral artery aneurysms.

Ischaemic colitis

The term ischaemic colitis can be used to cover ischaemic disorders of the large bowel caused by a number of different factors (Box 30.1). Generally speaking, ischaemia of the colon is caused by insufficient blood flow through the mesenteric vessels due to either thrombosis or embolus. Thrombosis of arteries to the colon is usually due to progressive narrowing of the vessels by atherosclerosis and may be accompanied by the development of a significant collateral blood supply. On the other hand, embolic occlusion of colonic vessels is usually sudden and therefore does not allow the development of collateral flow. In some cases ischaemia may occur in the absence of occlusive arterial disease, e.g. in patients with shock or congestive cardiac failure and following aortic reconstruction with ligation of the inferior mesenteric artery. This last cause is very unusual, however, as under most circumstances the entire colon can be adequately supplied by the superior mesenteric artery by way of the marginal artery. Various forms of vasculitis may also be responsible.

BOX 30.1 Causes of colonic ischaemia

Thrombosis – arterial or venous
- Arteriosclerosis
- Polycythaemia vera
- Portal hypertension
- Malignant disease of the colon
- Hyperviscosity syndrome due to:
  - platelet abnormalities
  - high molecular weight dextran infusion

Embolic from
- Left atrium (atrial fibrillation)
- Left ventricle (myocardial infarction)
- Atheromatous plaque in aorta

Vasculitis
- Polyarteritis nodosa
- Lupus erythematosus
- Giant cell arteritis (Takayasu's arteritis)
- Buerger disease
- Henoch–Schönlein disease

Surgical trauma to vessels
- Aortic reconstruction
- Resection of adjacent intestine

Non-occlusive ischaemia
- Shock – hypovolaemic or septic
- Congestive heart failure

'Spontaneous' ischaemic colitis

The degree of ischaemia in ischaemic colitis is highly variable and there are three clinical patterns:

- gangrenous ischaemic colitis
- transient ischaemic colitis
- stricturing ischaemic colitis.

Clinical features

Gangrenous ischaemic colitis

These patients are almost always elderly and usually have concurrent disease such as sepsis or cardiac failure. There is usually a history of acute onset of intense abdominal pain usually on the left side accompanied by bloody diarrhoea. On examination, the patient is severely ill and the abdomen is usually extremely tender with peritonism.

Transient ischaemic colitis

In this less dramatic form of the disease, patients are usually middle aged and may have evidence of peripheral vascular disease. There is usually a history of abdominal pain of several days' duration, and rectal bleeding is almost invariable. On examination, there is mild to moderate abdominal tenderness.

Stricturing ischaemic colitis

In these patients the clinical presentation may be insidious, although there may be a history of abdominal pain and rectal bleeding. Typically the patient will develop chronic abdominal discomfort and change of bowel habit and on examination there may be very little to find.

Diagnosis

Gangrenous ischaemic colitis

Plain abdominal radiographs in patients with colonic infarction show a blending of the mucosal folds, air in the wall of the colon and occasionally air in the portal venous system. If the colon has gone on to perforation, air under the diaphragm may be seen on an erect chest radiograph. Further investigation is usually not indicated as the patient will require urgent surgical intervention.

Transient ischaemic colitis

Here the abdominal radiograph will show 'thumb printing', which consists of multiple impressions of air due to submucosal oedema and haemorrhage. This is more clearly seen on a double-contrast barium enema. If colonoscopy is carried out, haemorrhagic oedema of the colonic mucosa will be seen. However, owing to the possibility of perforation, colonoscopy is not to be recommended if the diagnosis of ischaemic colitis is suspected.

Stricturing ischaemic colitis

Here the barium enema may reveal a relatively smooth stricture of the colon and on endoscopy thickened mucosa will be seen. Biopsy will show damage to the underlying muscularis propria associated with fibrosis.

Treatment

Gangrenous ischaemic colitis

When gangrenous ischaemic colitis is diagnosed then urgent laparotomy after adequate resuscitation is mandatory. The infarcted segment should be resected and the healthy bowel ends brought out as a colostomy or ileostomy and mucus fistula. Because of the gross contamination which often accompanies this condition the mortality is high.

Transient ischaemic colitis

If laparotomy is not indicated, treatment consists of general supportive measures, including intravenous fluids, parenteral nutrition where indicated and blood transfusion if the haemoglobin drops.

Stricturing ischaemic colitis

The treatment of this condition depends on symptoms and a colonic resection with primary anastomosis may be indicated.

Volvulus

Colonic volvulus or twisting of the colon is a relatively uncommon cause of large bowel obstruction in Western society, although it is much more usual in developing countries. The sigmoid colon is by far the most common site followed by the caecum. Very occasionally, volvulus of the transverse colon may occur.

Sigmoid volvulus

Sigmoid volvulus tends to affect elderly males, and typically the patient will be institutionalized with a previous history of chronic constipation, laxative dependency and unrelated medical problems.

Pathophysiology

An anticlockwise torsion of 180° is considered to be physiological. It may cause no symptoms and usually reverts spontaneously. However, if the posterior loop gradually fills with gas and stool and becomes heavier, it then changes its position and falls anterior to the empty loop, leading to a 360° anticlockwise torsion. Sigmoid volvulus may affect an individual for many years in a subacute recurring form but acute sigmoid volvulus is a surgical emergency because of the tight compression of the mesocolic vessels and massive distension of the colonic lumen.

Aetiology

There are probably many aetiological factors but the most important is probably a long sigmoid loop with a narrow mesentery leading to a predisposition to torsion. In addition, chronic constipation, a high-fibre diet and systemic neurological disease are important. In South America there is an association with Chagas disease.

Clinical features

In its chronic form the patient gives a history of intermittent lower colicky abdominal pain with abdominal distension which is relieved by the passage of flatus and loose stool. In the acute form, the patient will present as a large bowel obstruction with colicky abdominal pain, constipation and often massive distension. Vomiting is a late feature. On examination, the abdomen is distended and tympanic and may be tender over the dilated loop of colon. Tinkling bowel sounds can be heard initially but they vanish with either secondary ileus or perforation. Digital rectal examination reveals an empty distended rectum and there may be blood on the glove if gangrenous changes have set in.

Diagnosis

A plain abdominal radiograph (Figure 30.57) will confirm the diagnosis in 80% of cases. The diagnostic features include an enormously distended sigmoid colon arising from the left iliac fossa towards the right hypochondrium. It may lead to an elevated diaphragm. The loop has the appearance of a coffee bean and there is commonly a bird beak deformity at the site of the torsion. In late cases, peritoneal fluid is indicated by a ground-glass appearance, and there may be progressive distension of the small intestine with gas and fluid.

Complications

Acute sigmoid volvulus is complicated by gangrene and perforation of the twisted segment because of the tight compression of the mesocolic vessels and the massive distension. This may lead to faecal peritonitis. Occasionally, the massive distension may also lead to respiratory embarrassment.

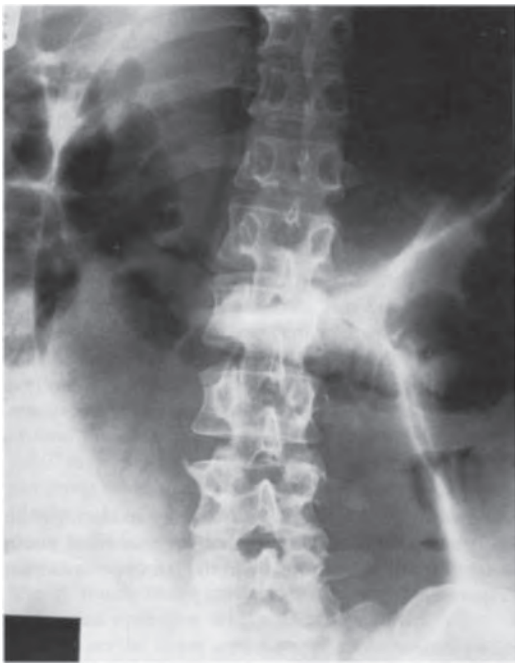

Figure 30.57 Plain abdominal radiograph of acute sigmoid volvulus.

Treatment

The first step should be to correct any fluid and electrolyte imbalance with intravenous replacement and then to attempt endoscopic reduction. This may be achieved by either a rigid sigmoidoscope or a flexible colonoscope and is successful in 80% of cases. A flexible instrument is preferable as the point of torsion may often be higher than the limit of the sigmoidoscope. Colonoscopy also allows for examination of the mucosal aspect for evidence of gangrene. If a flexible endoscope is not available and the rigid sigmoidoscope will not reach the point of torsion then it is possible to pass a blunt-ended flatus tube through the rigid sigmoidoscope to attempt a blind reduction.

It should be stressed that non-operative reduction does not constitute adequate treatment as the recurrence rate approaches 90%. Ideally, after successful endoscopic reduction, elective surgery should be carried out as quickly as possible as a one-stage sigmoid colectomy. However, if surgery is required urgently because of suspected strangulation or if non-operative decompression is unsuccessful, the standard treatment is resection of the sigmoid colon with a left iliac fossa colostomy and mucus fistula. Alternatively, the rectal stump may be oversewn as a Hartmann's procedure. In the relatively fit patient, however, it may be possible to do a sigmoid resection with on-table colonic irrigation followed by primary anastomosis but this should only be attempted when there is no doubt about the viability of the involved colon.

Caecal volvulus

The term caecal volvulus is really a misnomer as 90% of the cases are more accurately described as ileocolic torsion with only 10% involving the caecum alone. The propensity for caecal volvulus depends on a congenital abnormality of intestinal rotation in which the right colon does not fuse with the posterior abdominal wall but rather remains on a mesentery and is therefore highly mobile. It should be stressed that caecal volvulus is uncommon accounting for less than 1% of all cases of large bowel obstruction and only about 10% of all cases of volvulus.

Clinical features

There are three well-recognized modes of presentation. First, the patient may present with acute intestinal obstruction and this accounts for about 50% of cases. Second, the patient may present with rapid onset of acute abdominal pain and peritonitis secondary to gangrene of the affected segment of intestine. Third, a small number of patients present with chronic intermittent obstructive symptoms.

Diagnosis

Diagnosis in the acute stage is usually made on plain abdominal radiograph, which reveals a large air-filled viscus with an air – fluid level usually in the left upper quadrant (Figure 30.58).

Complications

The main complication as with sigmoid volvulus is gangrene leading to perforation and faecal peritonitis.

Treatment

Colonoscopic decompression is not usually successful and the mainstay of treatment is laparotomy with right hemicolectomy. Primary anastomosis is appropriate if there is no peritoneal soiling but if there is any doubt about the safety of an anastomosis, an ileostomy and mucus fistula should be fashioned. Another surgical option when the affected segment of bowel is completely viable is to carry out a caecopexy. This involves mobilizing the peritoneum of the right paracolic gutter to form a pouch into which the caecum can be inserted and sutured into place.

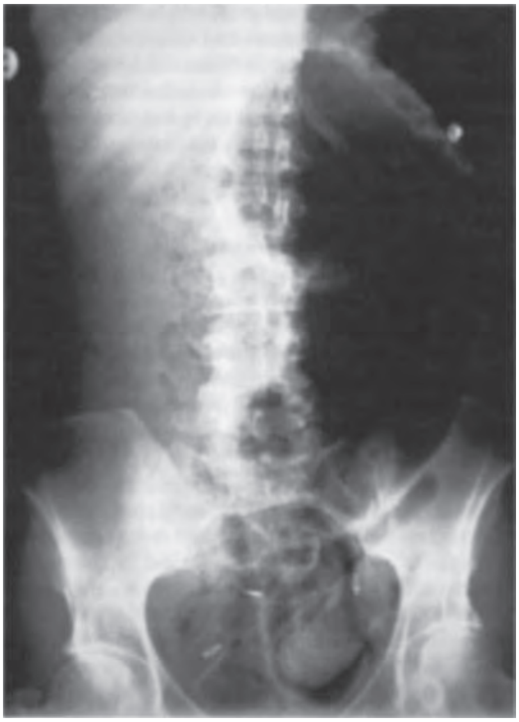

Figure 30.58 Plain abdominal radiograph of acute caecal volvulus.

Angiodysplasia

Angiomatous lesions of the bowel were first identified about 40 years ago with the introduction of angiography, and are now recognized to be relatively common. They characteristically occur in patients over the age of 60 years and are not usually associated with other angiomatous lesions of other viscera or of the skin. These lesions have been called angiodysplasias, angiomas, haemangiomas, arteriovenous malformations or vascular ectasias. Although they may occur anywhere in the gastrointestinal tract, they are commonest on the right side of the colon and histologically they consist of thin-walled vascular channels in the submucosa.

Aetiology

The cause of these lesions is unclear. They do not appear to be congenital and should be distinguished from hereditary haemorrhagic telangiectasia (Rendu–Osler–Weber syndrome). There are various theories as to the aetiology, including obstruction of submucosal veins as they pass through the muscle layers of the colonic wall and repeated episodes of bowel ischaemia with arteriovenous shunting. Both of these theories explain why the lesions should predominantly occur on the right side of the colon. This follows Laplace's law (tension is proportional to diameter and pressure) as the right colon has the widest diameter of the large bowel.

Clinical features

The clinical features of angiodysplasia depend on its tendency to bleed. Patients may present with anaemia or on some occasions with massive rectal bleeding.

Diagnosis

The main diagnostic modality is mesenteric angiography which characteristically shows an early draining vein parallel to a feeding artery (Figure 30.59). Colonoscopy may also detect the typical 'cherry red' spots which are characteristic of this condition (Figure 30.60).

Treatment

The most effective treatment for this condition is resection of the affected portion of bowel (usually a right hemicolectomy). In extreme conditions where the patient is actively haemorrhaging and the appropriate expertise is available, selective vasopressin infusion or transcatheter embolization with Gelfoam at arteriography may stop major haemorrhage. If the lesion is detected at colonoscopy then grasping it with diathermy forceps, lifting it away from the muscular wall and applying diathermy current may coagulate the abnormal vessels and prevent recurrent bleeding.

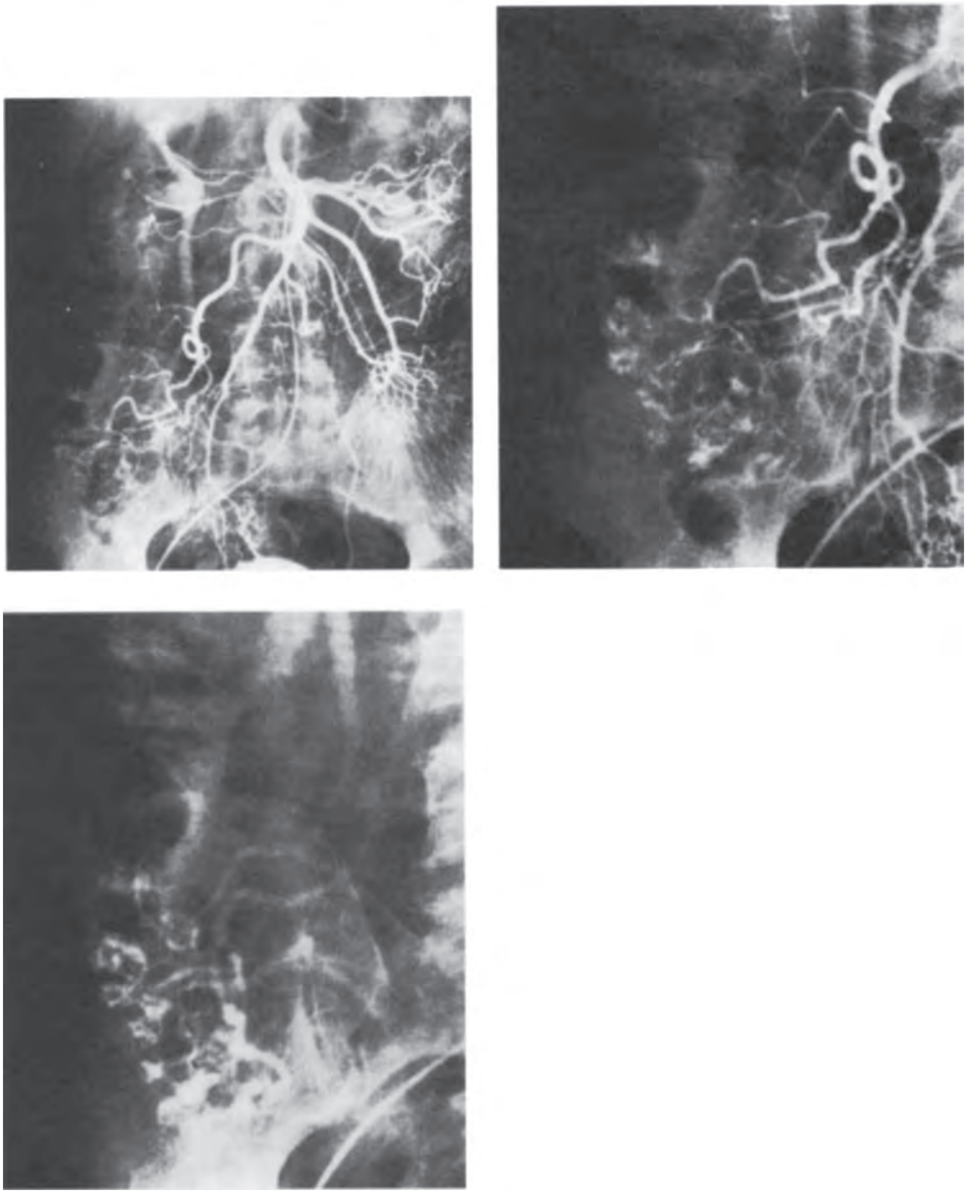

Figure 30.59 Angiographic appearances of angiodysplasia.

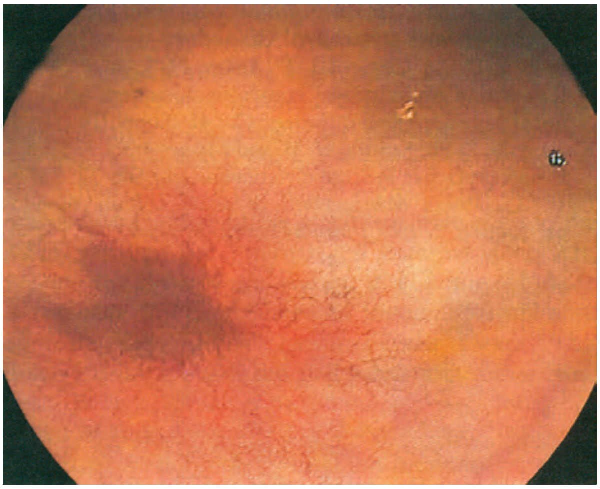

Figure 30.60 Colonoscopic appearances of angiodysplasia.

Visceral artery aneurysms

Aneurysms of the visceral arteries are relatively common but aneurysms of the colonic arteries are uncommon. There are various aetiological factors including congenital abnormalities, atherosclerosis, trauma, medial degeneration and forms of arteritis. Rupture of these aneurysms gives rise to severe abdominal pain and signs of internal haemorrhage. Successful treatment depends on prompt operative intervention.

CHAPTER 31

Disorders of the anal canal

KEN CAMPBELL

Anatomy

The anal canal is about 3–4 cm long. It passes slightly posteriorly, starting at the anorectal angle and ending at the anal verge. In the male, the anal canal is related to the bulb of the urethra anteriorly, and in the female to the perineal body and the vagina anteriorly. Laterally, it is related to the ischiorectal fossa containing the inferior haemorrhoidal vessels and pudendal nerve (Figure 31.1); posteriorly lie the coccyx and the puborectalis muscle. As described below, the anal canal is surrounded by the internal and external sphincter muscles.

The epithelium of the anal canal is columnar above the anal valves and squamous below them; the site of the anal valves is also known as the dentate or pectinate line and this indicates the mucocutaneous junction. The anal valves consist of pits that represent the openings of the anal glands, and the glands themselves lie in the plane between the internal and external sphincters, helping to lubricate the anal canal. The mucosa above the dentate line is arranged in longitudinal columns covering the internal haemorrhoidal plexus. This mucosa is loose, but at the anal valves it becomes fixed to the internal sphincter by the mucosal suspensory ligament of Parks.

Strictly speaking the epithelium immediately above the anal valves is not columnar but cuboidal and this zone, which is between 0.5 and 2 cm in length, is known as the anal transition zone. Here there is a high density of sensory nerve endings. Although the epithelium is squamous below the dentate line there are no hair follicles, sebaceous glands or sweat glands in the anal canal. These appear only at the anal verge.

The internal anal sphincter is a downward, thickened extension of the circular muscle fibres of the rectum and extends approximately 1 cm below the anal canal. It consists entirely of smooth muscle and is innervated by the pelvic autonomic plexus. The external sphincter, on the other hand, is made up of skeletal muscle that is arranged around the anal canal outside the internal sphincter (Figure 31.1). Posteriorly, the upper fibres of the external sphincter merge with those of puborectalis. Theoretically there are three components to the external anal sphincter complex but these are of little significance surgically. In the lower part of the anal canal there are longitudinal smooth muscle fibres and elastic tissue that extend through the lower fibres of the external sphincter to become attached to the perianal skin. These are extensions of the longitudinal muscle of the rectum.

As the pelvic floor is intimately related with the anal canal, it is also worth considering the anatomy of this structure. The pelvic diaphragm is formed by the levator ani, which arises from the sides of the pelvis and allows the passage of the urethra, vagina and anal canal. The innermost fibres are called puborectalis. This arises from the symphysis pubis and surrounds the vagina or

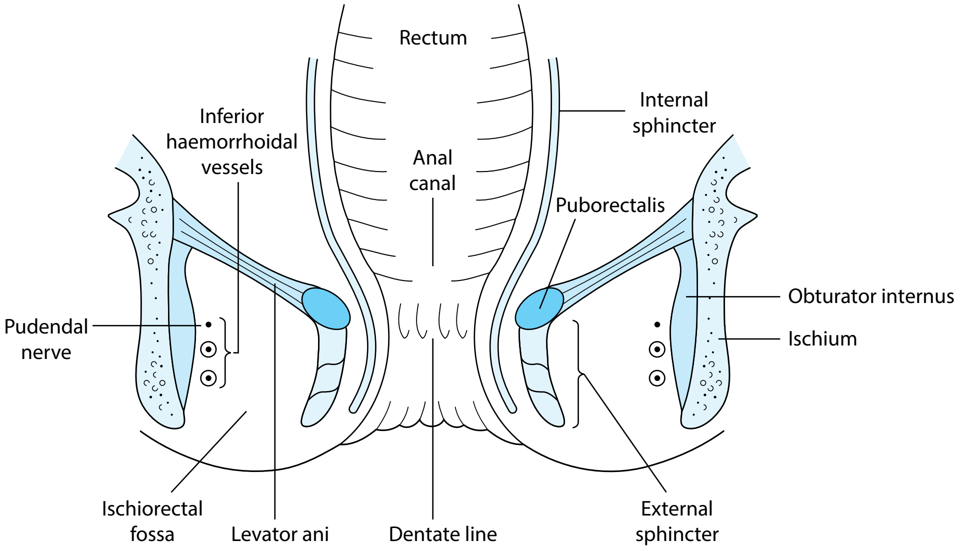

Figure 31.1 Anatomy of the anal canal.

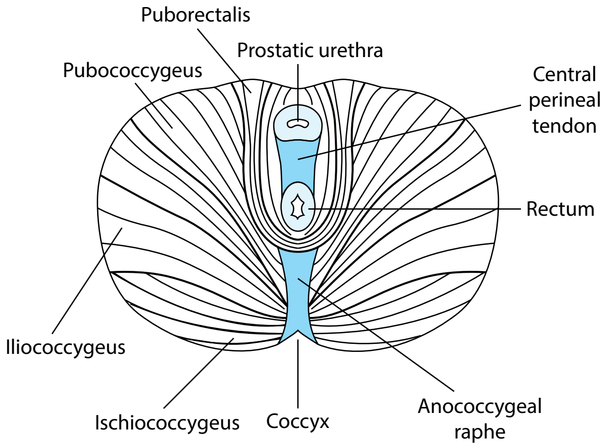

Figure 31.2 Anatomy of the pelvic floor.

prostate and the anorectal junction just above the sphincters and is then inserted into the symphysis pubis on the opposite side. Thus, it creates a sling that is deficient anteriorly. The rest of levator ani is made up of three parts: pubococcygeus, ileococcygeus and ischiococcygeus (Figure 31.2). Pubococcygeus arises from the pubis and is inserted into the coccyx. Ileococcygeus arises from the ileum and is inserted into the tissue between the anal canal and the coccyx (anococcygeal raphe) and into the coccyx itself. Ischiococcygeus arises from the ischial spine and is inserted into the coccyx and lower sacrum. Posteriorly, the pelvic floor is completed by piriformis, which arises on the pelvic surface of the sacrum and is inserted into the tip of the greater trochanter of the femur. On the perineal aspect of the pelvic floor is the central perineal tendon, which is a mass of fibrous tissue lying between the anal canal and the bulb of the penis or vagina. Into this is attached the transverse perineal muscles, which are divided into superficial and deep components. These muscles act as support for the pelvic floor. Deep to these structures lie muscle fibres joining the prostate or vagina to the anal canal that are known variously as levator prostatae, pubourethralis and pubovaginalis.

Nerve supply

Levator ani derives its nerve supply from the third and fourth sacral nerves as they pass from the pelvis through the pelvic floor. These nerves also supply the anal canal and perianal skin. The external anal sphincter complex is supplied by the pudendal nerve, which is derived from S2–4. This nerve leaves the pelvis between piriformis and ileococcygeus and re-enters it through the lesser sciatic foramen. It then runs forwards on the posterior surface of levator ani giving off the inferior haemorrhoidal nerve, the perineal nerve and the dorsal nerve of the penis. The inferior haemorrhoidal nerve supplies the external anal sphincter and perianal skin.

Blood supply

The blood supply to the anal canal comes from the inferior haemorrhoidal artery, which is a branch of the anterior portion of the internal iliac artery. It passes out of the pelvis between piriformis and ileococcygeus and via the greater sciatic foramen and then re-enters by passing over the sacrospinous ligament. It then runs in the ischiorectal fossa to supply the levator ani and sphincter muscles as well as the lower rectum and anal canal. The branches of the vessel that supply the skin of the anal canal have to pass through the internal sphincter muscle.

Venous drainage

The venous drainage very much follows the arterial supply but it is of interest to note that there is a very free communication between superior and inferior haemorrhoidal veins in the submucosal plexus of the anal canal and the rectum. Thus, both the anal canal and the lower rectum can drain directly into the systemic circulation via the internal iliac vein rather than through the portal system.

Lymphatic drainage

The lymphatic drainage of the upper anal canal is via channels around the rectum and then along the inferior mesenteric artery to the preaortic nodes. However, the lower anal canal below the dentate line drains to the perianal plexus and then on to the inguinal lymph nodes.

Physiology

The anal canal is a highly complex mechanism which, under normal situations, allows the individual to control the retention and evacuation of gaseous, liquid and solid rectal matter. There is, however, considerable individual variation and many people will at some point experience incontinence of liquid faeces or flatus. Slight leakage from the anal canal (soiling) is also not infrequent.

When faecal material enters the rectum there are three phases:

- *Accommodation*, in which the rectum slowly expands but both the internal and external sphincters retain their tone.
- *Sampling*, in which the rectal contents come into contact with the sensory lining of the anal canal (transitional zone) after temporary relaxation of the internal sphincter.
- *Defaecation*; although this is under voluntary control to a certain extent, when the volume of rectal contents reaches a critical point the urge to defaecate becomes overpowering and the tone in the external sphincter is inhibited.

The sensory component of incontinence is complex and most individuals are able to distinguish between gas, liquid and solid. Specialized nerve fibres are found within the anal canal and sensory endings in the levator ani complex of muscles have a role in controlling the urge to defaecate. Motor control of continence is exerted by a high-pressure zone in the anal canal (50–100 cmH_2O) produced by the combined tone of the internal and external sphincters. The angle of the anal canal and rectum is about 80° and is maintained by the action of puborectalis muscle. As indicated above, the initial stimulus for defaecation is distension of the rectum. This acts as a spinal reflex via a centre in the lumbosacral region, but cerebral control is exerted over this centre if circumstances are not convenient. Conditioning leads to a degree of cerebral control so that defaecation may take place only once a day even though the rectum contains faeces for much of the time.

During the act of defaecation, particularly in the squatting position, the rectum and anal canal form a straight line owing to straightening out of the anorectal angle. Abdominal pressure is raised and the external sphincter muscle is inhibited, allowing faeces to pass through the anal canal. This may be accompanied by a mass peristaltic action so that the whole distal colon is emptied. In some individuals, however, repeated straining may be necessary to pass several smaller segments of stool.

Investigations

Owing to the complexity of the sphincter mechanism, full investigation of the anal canal and its function requires considerable expertise and specialized equipment. The investigative procedures can be classified under the following headings:

- anal inspection and digital rectal examination
- endoscopy
- ultrasound
- manometry
- rectal sensitivity and capacity measurements
- electrophysiology
- radiology.

Anal inspection and digital rectal (and vaginal) examination

Anal inspection and digital rectal examination can give information about haemorrhoids, presence of anal fissure, perianal fistula, anal or rectal prolapse, rectocele, internal and external sphincter function, puborectal function and anal (and rectal) carcinoma. In women a combined rectovaginal examination is important in assessing a rectocele, anterior rectal cancer or anterior sphincter rupture. This investigation is mandatory for a first assessment.

Endoscopy

The anal canal can be examined endoscopically by means of a short rigid endoscope called, in the UK, a proctoscope (Figure 31.3). This is something of a misnomer, however, and the US term anoscope is more descriptive. This instrument allows visualization of the anal canal and lower rectal mucosa and is particularly useful for diagnosing internal haemorrhoids. It should not be used in the conscious patient when painful anal conditions such as fissure are present.

Ultrasound

Ultrasound is useful for visualizing the anal sphincters. The most widely used probe is a rotating 7 or 10 MHz probe within a water-filled plastic cone (Figure 31.4). This produces a 360° cross-sectional image when inserted into the anal canal. The ultrasound image that is produced images the internal sphincter as a well-defined hypoechoic layer and the external sphincter as

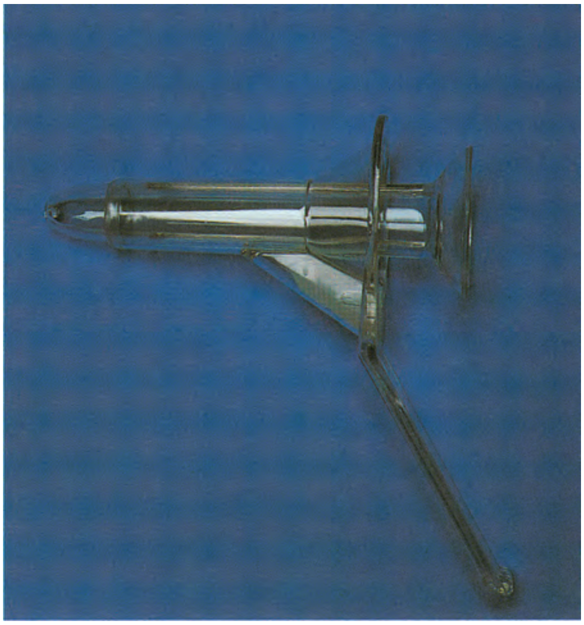

Figure 31.3 Proctoscope.

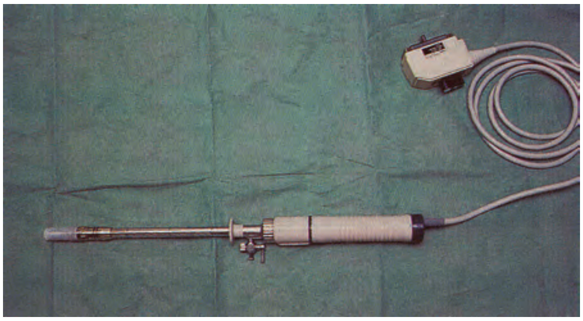

Figure 31.4 Anal ultrasound probe.

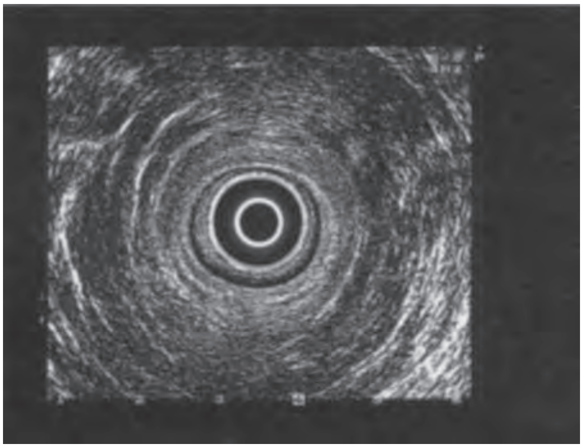

Figure 31.5 Normal ultrasound examination of the anal canal. The internal sphincter is seen as a hypoechoic (black) ring, and the external sphincter as an echogenic (white) ring.

a thick echogenic layer (Figure 31.4). In the lower part of the anal canal the internal sphincter is absent (Figure 31.5) and in the upper part the puborectalis muscle is seen (Figure 31.6). This investigation is very useful in detecting anal sphincter atrophy or anal sphincter disruption. It correlates well with findings during surgery. It is particularly useful in the evaluation of anal fistulas, determining the site and extent of sphincter involvement.

Technology has advanced in this area and the latest probes are oil filled with automated movement and image acquisition (Figure 31.7). This allows three-dimensional reconstruction and greatly increases the ability to later review and interrogate the scan (Figure 31.8).

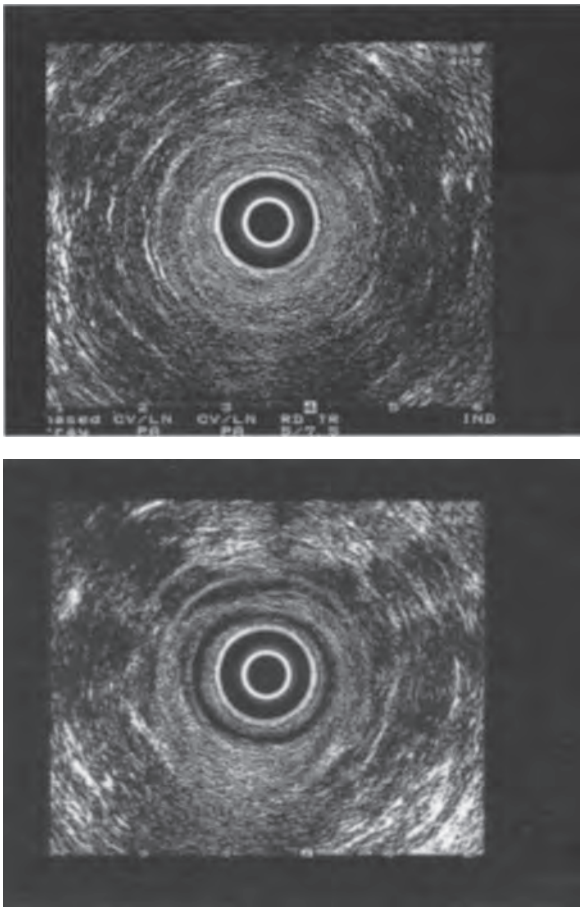

Figure 31.6 (a) Normal ultrasound examination of the lower anal canal; at this level, the internal sphincter is absent. (b) Normal ultrasound examination of the upper anal canal; here, the V-shaped fibres of the puborectalis muscle are seen posteriorly.

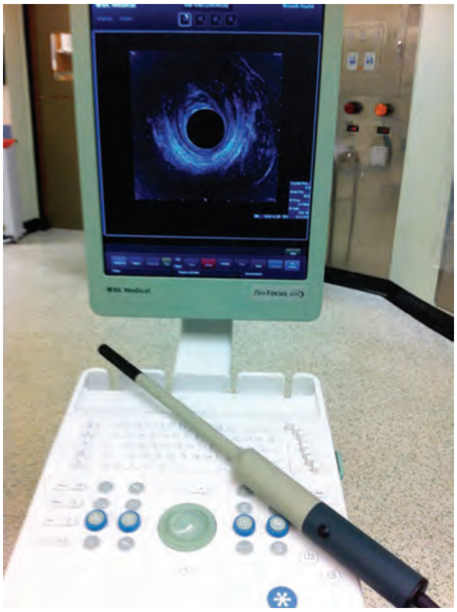

Figure 31.7 Three-dimensional ultrasound probe.

Anorectal manometry

Various devices are available for the measurement of pressures in the anal canal, but the recording device should not be >5 mm in diameter since larger catheters artificially raise anal pressure. The latest technology makes use of strain gauge catheters (Figure 31.9), which contain resistors on a metal diaphragm within a vacuum. Pressure on this diaphragm changes resistance, which is then converted to a pressure measurement. This can be used to produce either a static or an ambulatory measurement. Water-filled systems, however, may retain popularity owing to increased focus on infection control. The resting anal pressure is largely due to the internal sphincter, which is in a state of continuous contraction. This is highly variable, but a pressure of 50–100 cmH_2O is generally regarded as normal. Resting pressure is lower in women than in men and tends to decrease with increasing age. A normal squeeze pressure is in the region

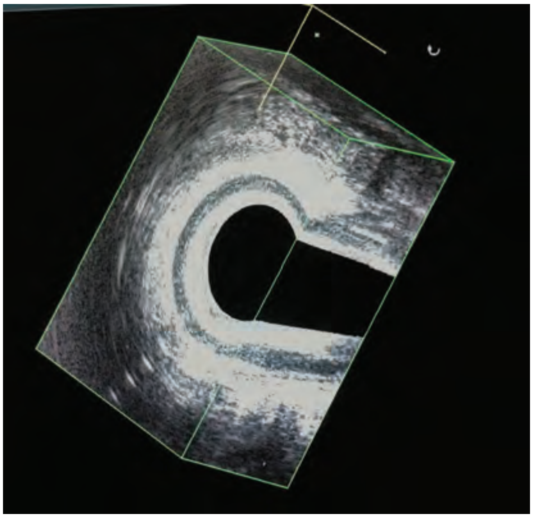

Figure 31.8 Three-dimensional ultrasound images.

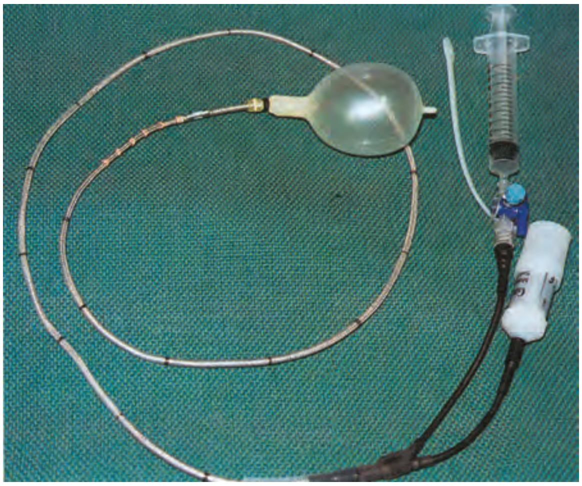

Figure 31.9 Anal manometry catheter.

of 250 cm H_2O for men and 100 cm H_2O for women. In general, patients with faecal incontinence have lower resting and squeeze pressures than continent patients, but there is poor correlation between the pressures and the severity of symptoms. There is also considerable overlap with the so-called normal range. Measures of fatigability may correlate better with incontinent symptoms. The underlying cause for the incontinence cannot be diagnosed on pressure readings alone.

Another useful application of anorectal manometry is testing for the rectoanal inhibitory reflex in patients with defaecation disorders. This is tested by balloon distension of the rectum along with simultaneous recording of the anal pressure. A positive reflex leads to a fall in resting anal pressure of 20%. Although this reflex is absent for a variety of reasons, for example spinal cord injury or anal atresia, a positive result effectively excludes Hirschsprung disease.

Rectal sensitivity and capacity

This investigation also has an important place in disorders of the anal canal. It can be performed by rectal balloon insufflation or a barostat system. The rectal balloon system is easier to use in clinical practice and planning. The advantage of the barostat system is that it can be used to measure rectal compliance, by using a non-elastic bag delivering constant pressures, therefore measuring rectal wall tension.

With the rectal balloon distension measurement, first rectal sensation, first urge sensation and maximal tolerated volume can be measured. In patients with urge incontinence, the first urge sensation is mostly lower than in continent patients. In patients with constipation the rectal sensitivity can be impaired.

Electrophysiology

Faecal or indeed urinary incontinence may be due to spinal or pelvic nerve damage and electrophysiological studies may be useful under these circumstances.

A common problem is incontinence related to child birth, which may be caused by stretch-induced damage to the pudendal nerves. This may be detected by measuring pudendal nerve motor latency. Here a disposable electrode is attached to the gloved index finger (Figure 31.10) and the finger is inserted into the rectum. The pudendal nerves are then palpable as cord-like structures passing around the ischial spines. Latency is defined as the time between the stimulus being delivered to the nerve at the finger tip and the impulse reaching a recording electrode measuring external sphincter contraction at the base of the finger. Normal pudendal motor latency is around 2 ± 0.2 milliseconds. Prolongation beyond the normal range suggests neuropathy and is, for example, associated with a poor outcome following sphincter repair. However, a normal result does not imply lack of neuropathy since only one limited element of nerve function is being tested. Perineal nerve motor latency can also be measured in a similar fashion. Spiral motor latency can be measured by transcutaneous stimulation at the LI and L4 levels with recording of the impulse at the external sphincter. The latency from LI is normally 5.5 milliseconds and from L4 is normally 4.4 milliseconds.

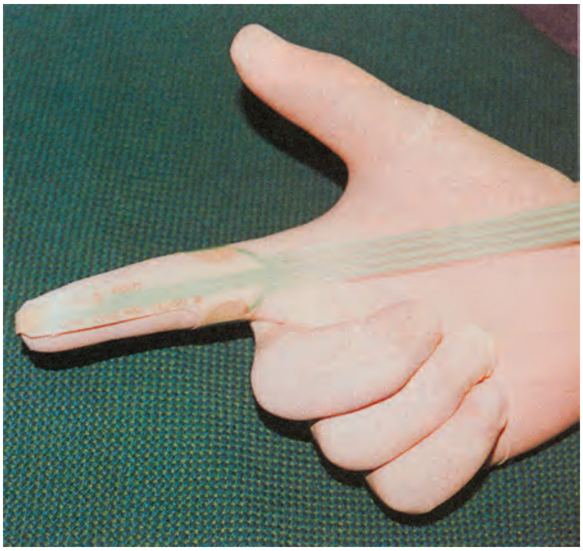

Figure 31.10 Finger-mounted electrode for measuring pudendal nerve motor latency.

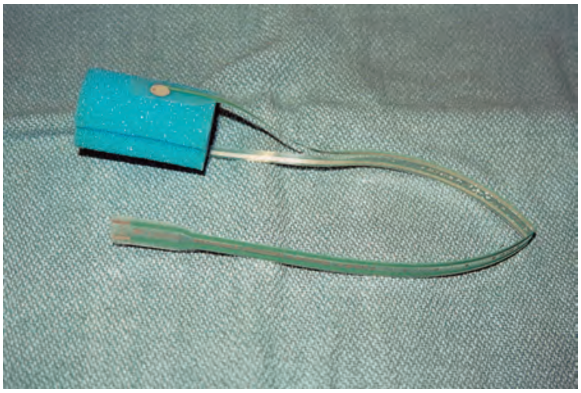

Figure 31.11 Coronal T_2 weighted magnetic resonance image demonstrating a cerebrospinal fluid (CSF) fistula in the left petrous temporal bone with CSF filling the left mastoid air cells (a).

Electromyography involves measuring muscle activity and the most accurate method of testing for denervation is single fibre electromyography. This involves inserting a platinum wire into the muscle. The changes brought about by denervation or reinnervation are quantified by calculating the fibre density, which is the average number of fibres recorded at 20 sites in the muscle. Needle electromyography is not used routinely in clinical practice owing to the discomfort of the test, and difficulty in interpretation. A simple sponge electrode (Figure 31.11) in the anal canal is useful in evaluating abnormal puborectalis contraction during straining (anismus).

Radiology

Defaecating proctography

Anal function is inseparable from rectal function and the most useful form of radiological assessment of this area is defaecating proctography (Figure 31.12). This involves using a thick paste impregnated with barium instilled into the rectum. Also, enteral contrast and vaginal contrast are instilled. The subject then sits on a commode and a video radiograph is taken during evacuation. Under normal circumstances, as straining begins there is a slight concavity of the anterior rectal wall produced by abdominal pressure. The pelvic floor then descends and the anorectal angle widens, the anal canal begins to open, to shorten and to become funnel shaped. A slight degree of rectal wall intussusception can be accepted as normal. This investigation is useful for evaluating rectocele, enterocele, rectorectal intussusception, pelvic floor movement and co-ordination. Thus, it is of value in investigating obstructed defaecation and also in the evaluation of incontinence.

Magnetic resonance imaging

This technique has become the gold standard in the evaluation of complex fistula *in ano*. Integrity and degeneration of the anal sphincter and pelvic floor can also be assessed. Dynamic MRI, giving an insight into the interaction and movement of the pelvic organs during straining and coughing, complements and in some cases may replace defecating proctography. A coil accommodating an upright patient is required for the best results in this type of assessment.

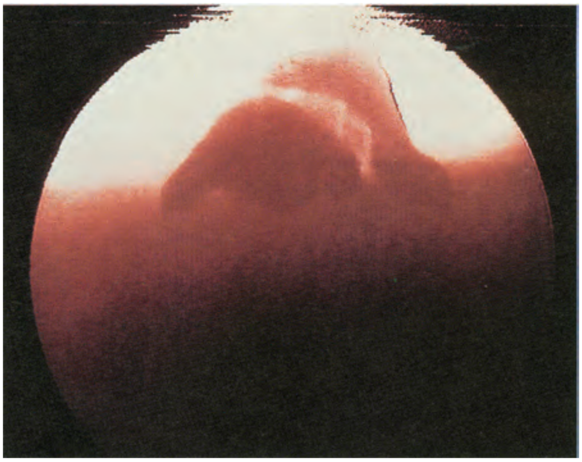

Figure 31.12 Defaecating proctography showing a degree of rectorectal intussusception.

Faecal incontinence

Faecal incontinence is potentially very disabling to patients. It ranges from occasional soiling to regular incontinence of solid faeces. Soiling is minor loss of faecal fluid or mucus confined to staining of underwear or small pads. Faecal incontinence can be either urge or passive incontinence. In the latter, patients are unaware of the need to pass a bowel movement and lose faeces without feeling it, whereas in the former the patient can feel the urge to defaecate but is not able to postpone the bowel movement until reaching a toilet.

Aetiology and pathology

Faecal incontinence can be due to various factors, which are summarized in Box 31.1. It is worth noting that patients with haemorrhoids suffer a mild degree of incontinence, presumably because of a certain amount of sensory impairment in the anal canal owing to loss or displacement of the anal cushions (see Haemorrhoids). These patients do not usually require any intervention, however, and the vast majority of patients presenting with serious incontinence have either an obstetric injury or an iatrogenic injury after anal surgery.

Usually, the woman with incontinence after childbirth gives a history of prolonged labour or a traumatic vaginal delivery usually with forceps. When there has been a severe perineal injury with anal sphincter disruption (third-degree tear) this is usually recognized at the time and immediate repair to the sphincter effected. If this is not recognized, however, the patient will develop severe incontinence soon after delivery. More commonly, the patient will gradually develop incontinence owing to an occult sphincter injury being unmasked by a lax pelvic floor and neuropathic sphincter failure owing to stretching of the pudendal nerves. Thus, the majority of patients with incontinence following single or multiple vaginal deliveries have a combination of nerve damage and direct damage to the pelvic floor.

Incontinence following anal surgery is usually related to laying open of a fistula *in ano* which has transgressed the external sphincter (see Perianal sepsis and fistula *in ano*). Lateral

BOX 31.1 Factors leading to anal incontinence

- Trauma
  - Obstetric injury
  - Surgical injury (after fistula surgery)
  - Accidental trauma (road traffic accident, war casualty)
- Anorectal disease
  - Haemorrhoids
  - Rectal prolapse
  - Anal or low rectal cancer involving the sphincter mechanism
  - Crohn's disease of the anus
- Factors causing diarrhoea
  - Inflammatory bowel disease
  - Infectious colitis
  - Malabsorption
- Congenital disorders
  - Treated imperforate anus
  - Hirschsprung disease
  - Spina bifida
- Neurological disorders
  - Pudendal nerve damage
  - Peripheral neuropathy
  - Stroke
  - Multiple sclerosis
  - Spinal cord damage
- Others
  - Behavioural
  - Faecal impaction
  - Encopresis

Table 31.1 Continence grading scale

Type of incontinence	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Requires pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

Data from Oliveira *et al.* (1996).

sphincterotomy for anal fissure, if done properly, is unlikely to give rise to frank incontinence but may lead to minor problems with control of flatus and mucus (soiling). Occasionally, however, an overenthusiastic sphincterotomy may cause external sphincter damage. Vigorous stretching of the anal canal for fissure or haemorrhoids may also give rise to incontinence owing to combined damage to the internal and external sphincters. Retraction of the sphincter to facilitate endorectal surgery is a risk factor, as is poorly controlled introduction of a circular stapler prior to anastomosis. Injudicious haemorrhoidectomy with excision of the internal anal sphincter is another source of leakage or incontinence.

Clinical assessment and investigation

In the first instance, it is important to establish the severity of the patient's symptoms. Intensive investigations and surgery for minor degrees of incontinence are not usually indicated as they are unlikely to be of value. A scoring system is useful for documenting the severity of incontinence and for estimating the response to treatment (Table 31.1).

A change in bowel habit may unmask an impaired sphincter and this must always be considered. A colonoscopy and biopsies may be required to exclude occult inflammatory conditions. It is also important to establish whether or not there is coexisting urinary incontinence as this suggests a neuropathological cause, and to find out about previous surgery and obstetric history. On examination the patient should be asked to strain in order to assess the presence of a rectal prolapse and the degree of perineal descent. Digital rectal examination will give information regarding resting anal tone and squeeze pressure and it may also be possible to feel a defect particularly in the anterior part of the external sphincter. The history should be a guide to the predominant site of dysfunction. Small quantity passive leakage only suggests an internal anal sphincter-based problem. This should be reflected in a low resting pressure on manometry with preserved squeeze pressure. Ultrasound may reveal deficiency or atrophy of the internal anal sphincter. Pelvic floor exercise is less likely to be of benefit and refractory cases may be considered for anal sphincter bulking injection. Urgency with full blown incontinent episodes implies external sphincter dysfunction. Manometry will generally reflect impaired squeeze pressures and ultrasound may identify a defect in the external anal sphincter. Frequently, the picture is mixed and the contribution of sensorineural changes is being increasingly recognized. Our current ability to accurately assess nerve function is quite limited. Pudendal nerve terminal motor latency and electrosensitivity are very crude assessments.

A trial of properly co-ordinated conservative measures should be the starting point for most patients. If a patient is not responding then a full set of investigations will be required. Ultrasound will document the site and extent of defects in the external or internal sphincter, and reveal occult injuries (Figure 31.13). There is no single objective test that will

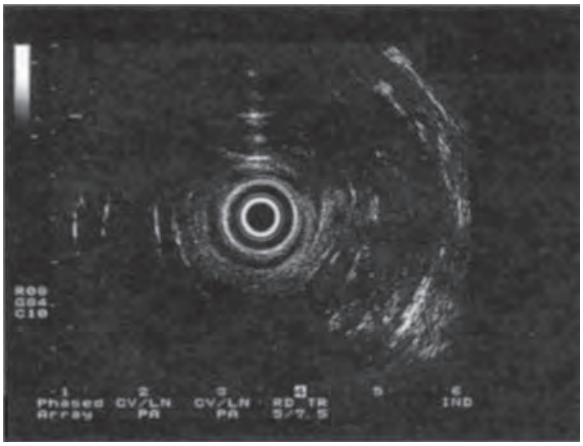

Figure 31.13 Anal ultrasound showing an anterior external sphincter defect. The crescentic echogenic band anteriorly is generated by the examiner's finger in the vagina.

determine the approach in this heterogeneous group of patients. The findings from anorectal manometry, pudendal nerve latency, rectal sensitivity and capacity, and ultrasound of the anal canal require to be critically appraised and correlated with the clinical features in establishing the best way forward for the individual patient. In refractory cases, defecating proctogram or dynamic MRI may suggest a role for an occult prolapsing disorder.

Conservative treatment

Medications

In many patients incontinence is related to loose stool; in such cases, antidiarrhoeal medication may be of value. In patients who are troubled by faecal leakage after defaecation, complete rectal emptying using suppositories (glycerin or bisacodyl) may be helpful.

Pelvic floor exercises and biofeedback

Other conservative approaches include pelvic floor exercises and biofeedback retraining; the combination of both is called pelvic floor rehabilitation. In biofeedback training, the patient is taught how to exercise the external anal sphincter by an anal sensor, and a balloon system is used to train the patient to recognize the stimulus of rectal distension.

Physiotherapists specializing in this area and able to deliver a comprehensive package of measures can effectively treat many incontinent patients without recourse to further intervention. Important areas to address include diet and lifestyle change, manipulation of stool consistency, pelvic floor strengthening, defaecation dynamics and abdominal wall strengthening. Advances in technology have allowed widespread use of electrostimulation and biofeedback retraining with suitable patients able to use the equipment at home.

Anal plug

An anal plug is effectively a modified tampon inserted through the anus. The top opens widely sitting in the rectum and can help some patients by simply blocking off the anal canal. Its use is limited in many patients by discomfort and in others by the device slipping out. Patients with impaired sensation sometimes tolerate the plug well and others find it useful as a back-up strategy in special situations. It is a simple device with little to be lost by a trial of use.

Rectal irrigation

This is a very old technique but regaining popularity. A convenient easy-to-use set of a pump and catheters has been manufactured (Peristeen, Coloplast; Irrimatic, B. Braun) that has made this option more attractive.

Reports are emerging of a possible rectal perforation with the technique, but, for motivated patients willing to persevere and learn to use it for their particular needs, it can be highly successful and by restoring control of their bowel function have a major impact on their quality of life. Overall, the technique is successful in about 60% of patients. It can be particularly helpful in patients with the difficult combination of incontinence and obstructed defaecation. For most incontinent patients retrograde rectal irrigation works well; on occasions antegrade irrigation by means of an appendicocaecostomy, transverse colostomy or sigmoid colostomy is resorted to, as used in refractory constipated patients.

Surgical interventions

Surgery can be divided into approaches to deal with contributory problems such as prolapse, approaches dealing directly with the sphincter complex such as anterior sphincter repair and techniques to augment the sphincter such as gracilis neosphincter.

An alternative is to target the sensorineural system and this approach, sacral nerve modulation, is the one that has advanced the most in recent years. With its lack of any substantial adverse effects many would currently opt for a trial of this approach in almost any patient with significant lifestyle compromise despite full trial of the above detailed conservative measures. The recent emergence of percutaneous tibial nerve stimulation as a potentially less costly means to achieve neuromodulation is of interest and further experience will determine where this will fit into future treatment algorithms.

Surgery for prolapsing disorders

If any doubt persists regarding the role of a prolapsing disorder or the exact nature of the prolapse then an examination under anaesthesia is well worthwhile. Any form of prolapse can potentially lead to incontinence. There are several mechanisms underlying this. Prolapse may repeatedly trigger the sampling reflex, leading to inhibition of internal anal sphincter tone. Many cases of prolapse appear to generate high-pressure waves that overcome sphincter pressure. In full thickness prolapse the sphincter is physically stretched by the prolapse. There is often an accompanying straining disorder leading to perineal descent and pudendal neuropathy.

The technique required to deal with the prolapse must be carefully selected to avoid exacerbating the incontinence problem. When possible, this would be an abdominal technique as perineal procedures will inevitably interfere with rectal compliance and reservoir function (see Chapter 30).

The situation with full thickness prolapse is straightforward in that surgery is clearly necessary and only the technique is a matter of debate. In mucohaemorrhoidal prolapse the situation is less clear. There may be a delicate balance between improving or exacerbating the situation with no test to quantify this.

Some recent interest has surrounded the role of internal intussusception in the aetiology of incontinence as well as in obstructed defaecation. Procedures such as ventral mesh rectopexy offer a more complete restoration of anatomy than posterior rectopexy with better functional results. A great deal of work is required in this expanding area. What is clear is that incontinence and difficulties with evacuation often share common aetiological factors and coexist more frequently than previously appreciated. The interface with gynaecological disorders is expanding. A more sophisticated, wide-ranging, multidisciplinary assessment is going to be required for these patients, but may yield a better outcome for the future.

Haemorrhoids and incontinence

Treatment options in haemorrhoids are dealt with separately. Haemorrhoidal prolapse may be responsible for a degree of relatively small quantity passive faecal leak as well as mucus leakage and irritation. Their exact contribution in a case of incontinence needs to be carefully assessed. The incidence of urgency following stapled anopexy procedures would suggest caution in selecting this approach for a patient with compromise in continence.

Perianal injectable bulking agents

The inner ring or internal anal sphincter muscle keeps the anus closed at all times except when opening the bowel. A treatment has been developed to treat faecal incontinence that involves injecting a substance into or near this muscle to make it bulkier so that the anus closes better. It has been advocated as a simple and safe option.

A silicone biomaterial (PTQ) was shown to provide some advantages and was safer in treating faecal incontinence than carbon-coated beads (Durasphere) in the short term. Similarly, there were short-term benefits from injections delivered under ultrasound guidance compared with digital guidance. Carefully chosen individual patients can certainly benefit from this approach, although evidence-based assessments have not been convincing. Further studies to determine the optimal site, quantity and material for injection are required.

Anterior sphincter repair

In patients with a significant anterior sphincter defect, direct repair can be effective, although initial good results will tend to deteriorate with long-term follow-up. Around 50% of patients have long-term success. The technique involves making an incision anterior to the anal canal and carefully dissecting out the external sphincter down to the levators. Usually there is a fibrous band at the site of the muscular defect (Figure 31.14). This is transected and the cut ends of the sphincter are overlapped and sutured together (Figure 31.15). Many surgeons will supplement this with an anterior levatorplasty, which is carried out by suturing together the two sides of the levator ani muscle. Most surgeons leave the wound at least partially open in view of the high incidence of infection. The patients must have a laxative regime postoperatively to avoid any straining.

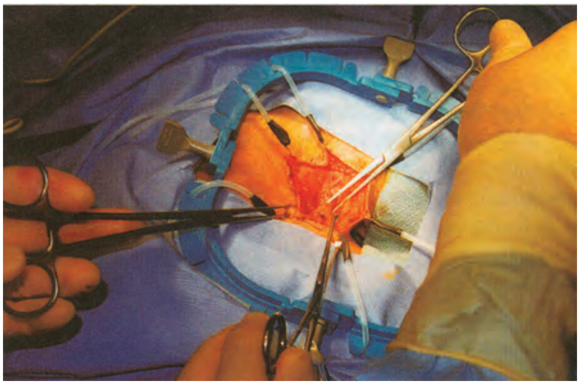

Figure 31.14 Fibrous band at the site of an anterior sphincter defect indicated by the Allis forceps.

Postanal repair

This operation was originally devised in order to restore the normal angle between the anus and the rectum and involves making an incision posterior to the anal margin, dissecting in the intersphincteric plane and plicating the puborectalis muscle. This operation tends to be performed when the sphincter appears to be intact. The early results tend to be good, although the mechanism whereby improvement occurs is controversial. However, long-term follow-up indicates that function deteriorates and the operation has lost favour in recent years.

Total pelvic floor repair

This operation combines a postanal repair with anterior sphincter plication and levatorplasty. It may be more effective than postanal repair, and can be performed in stages or as a single procedure.

Sacral nerve modulation

This is a technique originally developed for urinary incontinence. A low-level electrical stimulus is applied via a percutaneous electrode placed through one of the sacral foramina, preferably the third (Figure 31.16). Although the term sacral nerve stimulation is frequently used, the process by which an effect occurs is unknown. Modulation of reflexes and nerve activity is felt to be the mechanism. The only measurable changes observed

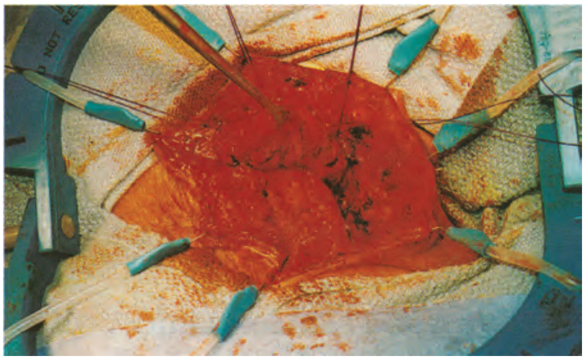

Figure 31.15 Overlapping anterior repair of the external anal sphincter.

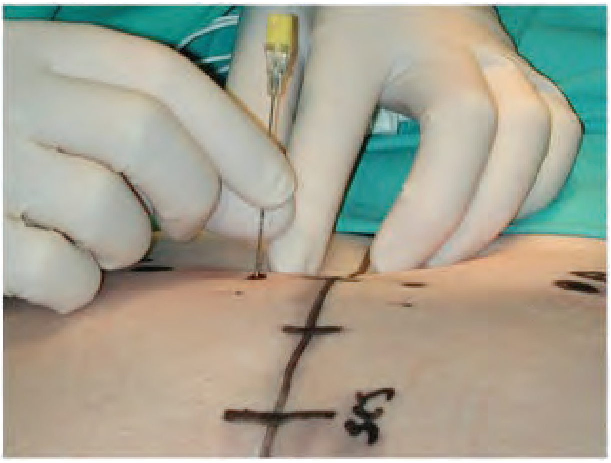

Figure 31.16 Probing sacral foramina for lead placement in sacral nerve neuromodulation.

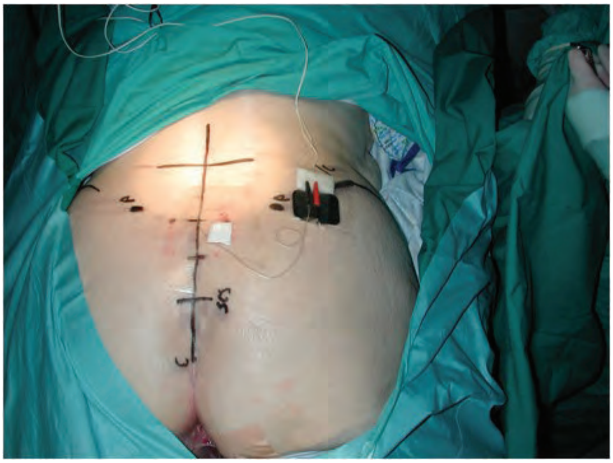

Figure 31.17 Temporary lead in place for test sacral nerve neuromodulation.

are sensory rather than manometric. A test phase (peripheral neural evaluation) is undertaken with an external generator attached to the electrode (Figure 31.17). A sensory response evidenced by a tingling sensation around the anus, or a motor response evidenced by a 'bellows' movement of the perineum, is sought. The patient's clinical response is then evaluated for a period of up to 3 weeks. If an improvement >50% is observed the patient is offered a permanent implant.

A quadripolar electrode is inserted and connected to a pacemaker implanted in the buttock. A success rate of the order of 80% is noted in faecal incontinence, with a very low level of adverse effects. Although the generator is expensive, the test phase allows accurate prediction of which patients will benefit. Sacral nerve modulation is now recommended by the National Institute for Health and Clinical Excellence, which advises on cost-effective evidence-based approaches and provides clinical guidelines in the UK (see Estimating the long-term costs of treatment options in incontinence).

Pudendal nerve modulation

Pudendal nerve modulation is a new technique which may be suitable for patients who have unsuccessful treatment with sacral nerve modulation. Trials are being carried out at the moment.

Percutaneous tibial nerve stimulation

Percutaneous tibial nerve stimulation has come in to use for the treatment of lower urinary tract dysfunction since 2001 and for chronic pelvic pain since 2003. Since 2010 there have been a few studies on treatment in patients with faecal incontinence. In this technique a needle is inserted 3–4 cm proximal to the medial malleolus, between the posterior margin of the tibia and the soleus muscle tendon, and an electrode is placed on the same leg near the arch of the foot. Both are connected to a stimulator. A series of 12 stimulations lasting 30 minutes are applied, separated by no more than 7 days. Success rates of 40–60% have been seen in initial studies.

Dynamic graciloplasty

For many years the gracilis muscle has been used for anal sphincter supplementation (unstimulated graciloplasty), the operation having been originally devised for children with anorectal atresia. In adults, however, straightforward transposition is not associated with particularly good results because the gracilis muscle can only contract voluntarily and is not able to maintain contraction for more than 1 minute. The operation of electrically stimulated gracilis neosphincter, the dynamic graciloplasty, has therefore been developed. The stimulation is provided by two intramuscular electrodes and a stimulator/pacemaker. This operation may be used for patients in whom sphincter repair has failed or is inappropriate, but it may also be used for those who do not have an anal sphincter, e.g. in anorectal agenesis or after abdominoperineal excision of the rectum (Figure 31.18). The results of this operation are difficult to assess objectively but about two-thirds of patients who have undergone the procedure appear to be satisfied with the results achieved. The success rate is lower in patients with anal atresia, most probably because of malformation of neurological, pelvic and sphincter structures in these patients. The technique is surgically demanding with significant morbidity levels. It is best confined to high-volume specialist centres.

Artificial bowel sphincter

An artificial plastic sphincter that can be inflated and deflated by the patient can be inserted around the anal canal (Figure 31.19). The most commonly used device is a modification of the artificial urinary sphincter that is inserted via the perineum. The plastic cuff is connected to a control pump placed in the labia or in the scrotum. This pump is connected to a pressure-regulating balloon

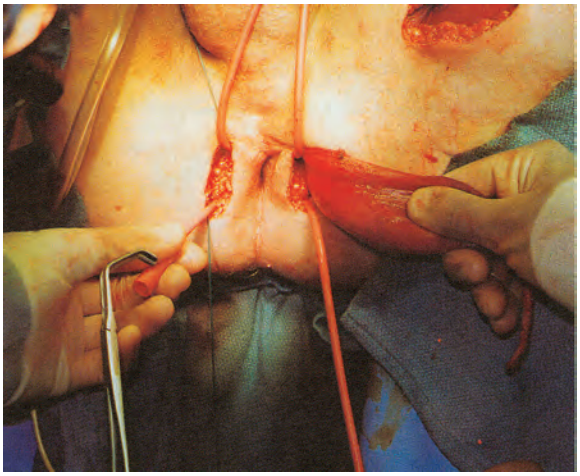

Figure 31.18 Electrically stimulated gracilis neosphincter showing the gracilis muscle mobilized in preparation for plication around the anal canal.

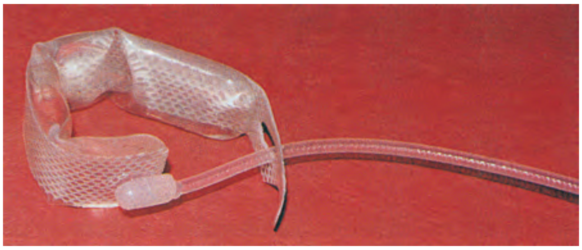

Figure 31.19 Artificial anal sphincter.

placed behind the pubic bone, above the bladder. Success rates of 60% in the long-term can be achieved in terms of continence, although a variety of other problems are experienced by patients. Infection requiring removal of the device occurs in around 20% of cases. Placement of the prosthesis via the abdomen with full mobilization of the rectum may be associated with a lower infection rate, but requires more major surgery.

Although continence is achievable with these sphincter augmentation or encirclement approaches difficulties with evacuation are common and frequently significantly impair the overall quality of life achieved. The sphincter complex has sophisticated dual functionality in terms of maintaining continence and facilitating evacuation.

Estimating the long-term costs of treatment options in incontinence

The 5 year cumulative costs for conservative treatment in faecal incontinence is €3234. The estimated 5 year cumulative cost for colonic irrigation €573. The cost for an anterior anal sphincter repair is €5327. The cost for peripheral neural evaluation and test period are €4053. The 5 year cumulative cost for a sacral nerve modulation implant is €22 150, compared with €33 996 for an end-colostomy, and €31 590 for a DGP. The 5-year cumulative costs of an artificial bowel sphincter is €29 740.

Haemorrhoids

The term haemorrhoids or 'piles' means different things to different people and many patients will use these words to describe a wide variety of anorectal conditions. To the surgeon, however, it refers to abnormalities of the vascular cushions of the anus.

Pathology and aetiology

The anal cushions consist of three spaces filled by arteriovenous communications supported by a fibrous matrix and smooth muscle lying within the anal canal. This allows the anal lining to expand during defaecation but yet to form a complete seal when the anal canal is closed. The arterial supply for these cushions comes from the superior, middle and inferior rectal arteries. Haemorrhoids are thought to result from degeneration of the smooth muscle and fibroelastic tissue that supports the cushions, allowing them to prolapse into the anal canal. However, the underlying reasons for this degeneration are not clear and although constipation and straining at stool have been implicated, the evidence for this is patchy. There is a family history in about 50% of cases and it is therefore possible that a genetic predisposition exists.

Clinical features

The most common symptom is bleeding at defaecation. Commonly this is bright red and follows immediately after defaecation. Typically this is painless but may be quite profuse and frightening for the patient. Other symptoms include perianal swelling, pruritus and minor soiling. Pain from haemorrhoids is associated with complications. Clinically, haemorrhoids can be classified into four groups:

1. internal haemorrhoids presenting with bleeding alone (first degree)
2. haemorrhoids which prolapse on defaecation but reduce spontaneously (second degree)
3. haemorrhoids which prolapse and require manual reduction (third degree)
4. irreducibly prolapsed haemorrhoids (fourth degree).

Thus, on examination the external appearances will depend on the degree of prolapse and the anal canal may in fact look normal. Skin tags around the anal orifice are common and mucosa may be seen to prolapse (Figure 31.20). Digital rectal examination is generally normal. The main diagnostic test is proctoscopy, which gives a good view of the internal anal cushions. It is also essential to examine the rectum with a rigid or flexible sigmoidoscope at least to exclude other lesions.

Investigations

As far as making the diagnosis of haemorrhoids is concerned, investigations other than those mentioned above are unnecessary. However, if there is any doubt about the source of bleeding then a full colonic examination in the form of a flexible sigmoidoscopy and barium enema or a total colonoscopy should be carried out. This would be indicated when there are other symptoms such as change of bowel habit or lower abdominal pain or if the patient is in the high-risk age range for colorectal cancer (i.e. over 50 years of age).

Complications

The complications of haemorrhoids include thrombosis, massive haemorrhage and faecal incontinence.

Thrombosis

When haemorrhoids become irreducible, intravascular thrombosis and oedema may ensue owing to strangulation of the blood supply. This gives rise to severe pain and on examination swollen bluish external haemorrhoids will be seen. Occasionally these may become gangrenous.

Massive bleeding

Very occasionally patients may bleed so profusely from haemorrhoids that they become shocked and require resuscitation

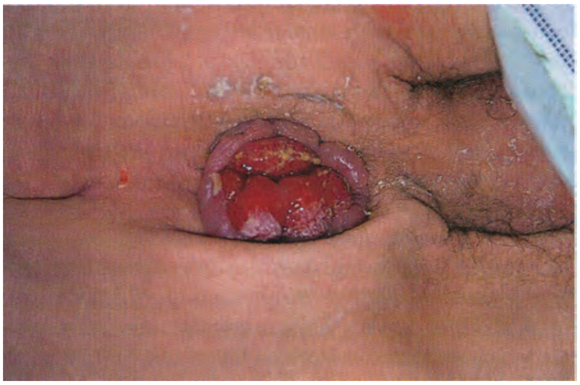

Figure 31.20 Prolapsing haemorrhoids.

with blood transfusion. More commonly, although still relatively unusually, a patient may develop iron-deficiency anaemia from regular bleeding episodes. Attributing iron-deficiency anaemia to haemorrhoids should generally only take place after full investigation to exclude other sources.

Incontinence

Pruritus and minor soiling are relatively common owing to leakage of mucus and liquid faeces from the rectum. This is thought to be due to a poor sealing mechanism owing to displacement of the anal cushions. This may be compounded by a certain amount of sensory impairment in the anal canal. Under most circumstances these symptoms are not particularly disabling but occasionally patients may find them extremely troublesome. If this is the case, the patient should be fully investigated for incontinence as there may be some other underlying cause.

Treatment

The majority of patients with symptomatic haemorrhoids do not need active intervention. Often reassurance after exclusion of serious disease is sufficient. If the patient is finding that constipation or straining is an important feature then bulk laxatives may be of value. Topical ointments may help by providing lubrication but their value is unclear. Diltiazem cream 2% has benefits for reduction of haemarrhoids. It has to be applied twice a day for 6 weeks. If patients have a benefit, they continue for another 6 weeks. Active intervention for haemorrhoids can be divided into two broad areas: (1) outpatient procedures and (2) surgery.

Outpatient procedures

Injection sclerotherapy

For many years injection of sclerosant (most commonly 5% phenol in almond or arachis oil) has been used for the treatment of haemorrhoids. This is injected using a long needle via a proctoscope and 3–5 mL of sclerosant should be injected into the submucosa well above the dentate line at each haemorrhoidal site. The underlying aim is to produce a fibrous reaction within the anal cushion to reduce the degree of prolapse. Care must be taken not to inject too superficially, as this will lead to ulceration, or too deeply, as this will be ineffective. If the injection is too deep it is also possible to damage the prostate or the seminal vesicles and perirectal sepsis has been reported.

Rubber band ligation

An alternative to injection sclerotherapy is rubber band ligation and indeed in randomized trials it has been shown to be more effective. This involves placing tight rubber bands around the prolapsing cushion at least 1.5 cm above the dentate line. There are various devices for achieving this but most are used via a proctoscope. Perhaps the simplest device is a suction tube to which the band is mounted (Figure 31.21). The mucosa is then sucked into the tube and a special triggering device is used to push the band off the end of the tube. More than one band can be inserted at one time although it may be necessary to repeat the procedure. The surgeon should be very careful to apply the band above the dentate line as failure to do this will lead to immediate severe pain. If this happens it is necessary to remove the band by cutting onto it with the tip of a scalpel blade, and this may sometimes necessitate a general anaesthetic. After the procedure patients should be warned to expect some bleeding at between 5 and 10 days when the necrotic cushion separates. They may also expect to have some aching, which may be relieved by warm baths and non-steroidal anti-inflammatory drugs.

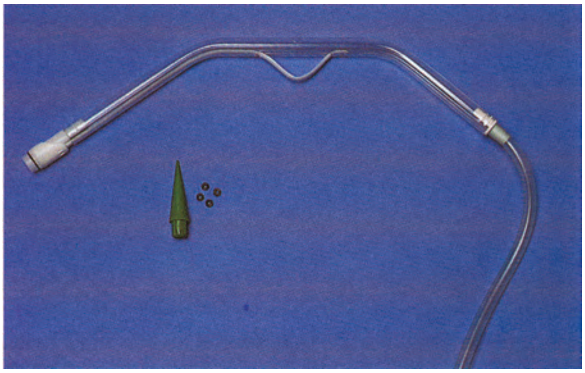

Figure 31.21 Rubber band ligation device for haemorrhoids.

Other outpatient techniques

Bipolar coagulation, infrared photocoagulation, laser photocoagulation and cryotherapy have all been used but none has gained popularity.

The true efficacy of outpatient procedures is not clear. There have been a number of comparative randomized studies that tend to favour rubber band ligation, but unfortunately stratification for severity of disease and the use of no-treatment controls has been lacking. There is little doubt that these procedures have a strong placebo effect and further research is required to establish their precise role in the management of haemorrhoids.

Surgery

In patients who have had failed to benefit from outpatient treatment, the surgical approach becomes necessary. In addition there is a feeling among many colorectal surgeons that patients with severely prolapsing haemorrhoids or in whom bleeding is a major concern should have primary surgical intervention. Currently, there are two widely used surgical approaches: haemorrhoidectomy and stapled anopexy. Haemorrhoidal artery ligation or dearterialization is a more recent approach that is gaining popularity.

Haemorrhoidectomy

There are many different varieties of haemorrhoidectomy but the basic principle is to excise the prolapsing anal cushions while maintaining mucocutaneous continuity between the areas of excision. Each haemorrhoid is grasped close to the mucocutaneous junction in turn and excised in the plane immediately outside the internal sphincter using diathermy. Associated skin tags are included in the excision. If this is done carefully the pedicle will merely consist of a thin strip of mucosa and can be transected directly with diathermy, although some surgeons still prefer to ligate the pedicle. Variations include operating position and whether the mucosa is closed by suture or left open. Lithotomy position is most common in UK practice with prone or left lateral most common in the USA.

Traditionally, after haemorrhoidectomy patients were kept in hospital until their bowels had moved but with careful preparation and community support haemorrhoidectomy can be carried out as a day case. It is even possible to perform the procedure under regional anaesthesia. Steps to diminish pain postoperatively and particularly at the time of defecation include the use of metronidazole, laxative regimens and the use of topical glyceryl trinitrate (GTN) or diltiazem. There is some support for mucosal closure, as in the Ferguson haemorrhoidectomy, compared with the open approach, as in the Milligan–Morgan haemorrhoidectomy, but evidence is not strong in any of these areas.

Stapled anopexy

The term stapled haemorrhoidectomy is inaccurate since the intention is not to excise the prolapsed haemorrhoidal cushions but relocate and fix them; the term stapled anopexy is more appropriate, although less popularly applied. The procedure has attracted a great deal of interest in the last few years. The principle of this operation is to carry out excision of a circumferential strip of mucosa above the dentate line and to simultaneously close the defect. This pulls the mucosa and therefore the anal cushions back up into their normal position, thus restoring the anatomy of the anal canal. This is done using a specially designed proctoscope and circular end-to-end anastomosing stapler.

A purse string is inserted in the rectal mucosa 3 cm above the dentate line, the stapler is inserted and the purse string tightened around the centre rod (Figure 31.22). The stapler is then fired, simultaneously excising the mucosa and stapling the two cut ends together (Figure 31.23). After excising a cam 'doughnut' a circumferential staple line should be left 1 cm above the dentate line. If the stapling is performed too proximally it will be ineffective in elevating the anal cushions, and if performed too distally will risk interference with the sphincter complex. Immediately after the procedure the staple line must be inspected for bleeding points, which can be oversewn. In theory, confining the surgery to the less sensate area above the mucocutaneous junction should be less painful and randomized controlled trials have consistently shown an advantage to the stapled technique in terms of pain. Haemorrhoidectomy has an unfortunate reputation for pain among the general public with many postponing or avoiding intervention. Although certainly not painless, stapled haemorrhoidectomy does appear to increase patient acceptability and may help facilitate day-case surgery. In expert hands the technique appears at least as effective as excisional haemorrhoidectomy but there may be an increased risk of recurrent prolapse over time. It has not been possible to demonstrate a functional advantage despite a more restorative approach. Although large numbers of cases have now been performed uneventfully, care is required as perforation and complete closure of the rectum have occurred (see also Haemorrhoids and incontinence).

Haemorrhoid artery ligation/dearterialization

The latest approach in the quest for an effective but painless treatment for haemorrhoids involves identifying and ligating the arterial inflow to the haemorrhoidal pedicles. This is achieved by using specially designed proctoscopes incorporating a Doppler device and facilitating guided haemorrhoidal artery suture and ligation. The latest variation allows expansion of the technique to treat haemorrhoidal prolapse by suture fixation (rectoanal repair).

The technique is disseminating rapidly with several supportive publications. It appears to be well tolerated and have minimal adverse consequences so far.

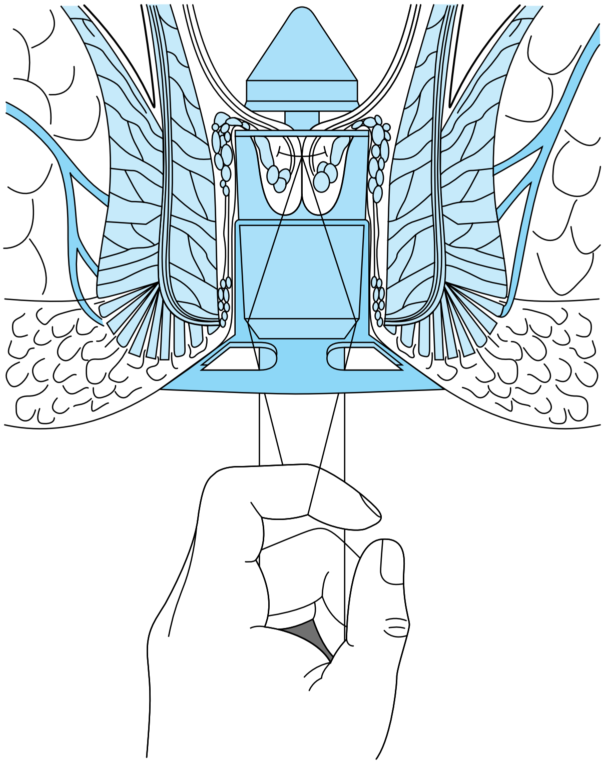

Figure 31.22 Stapled anopexy. Prolapsing rectal mucosa is drawn into a circular stapling gun. Simultaneous excision and stapling draws the anal canal back into an anatomical position.

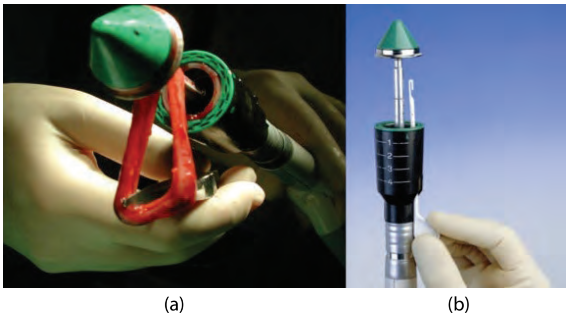

(a) (b)

Treating complications of haemorrhoids

The patient with strangulated thrombosed haemorrhoids usually requires hospitalization for adequate analgesia and bed rest. Cold compresses applied directly to the haemorrhoids are also beneficial. Surgeons are divided as to whether or not early haemorrhoidectomy should be carried out in these patients and often an individual decision has to be made on the basis of the severity and duration of the symptoms. Those against intervention argue that following an episode of strangulation haemorrhoid symptoms often resolve spontaneously. Occasional cases of portal pyaemia have been reported.

A case of prolapsed thrombosed haemorrhoids need to be distinguished from that of a thrombosed external haemorrhoid. This is another misnomer as the latter condition is simply a haematoma forming in relation to the external haemorrhoidal plexus and quite separate from the anal cushions. Incision and evacuation of the clot will rapidly relieve symptoms.

Massive bleeding usually requires haemorrhoidectomy and should be distinguished from the occasional case of variceal bleeding secondary to portosystemic shunting at the anorectal junction. Minor degrees of incontinence usually respond well to carefully performed haemorrhoid surgery.

Perianal sepsis and fistula *in ano*

Perianal sepsis and fistula formation may be associated with a number of disease processes including Crohn's disease, malignancy, tuberculosis, pilonidal sinus and trauma. In the majority of patients, however, the condition is idiopathic.

Pathology and aetiology

Central to current thinking regarding perianal sepsis and fistula formation are the anal glands. These glands are situated in the intersphincteric space and open into the anal canal at the dentate line via a duct that transverses the internal sphincter. The function of these glands is not clear but as they secrete mucin they may have a lubricant function. It is thought these glands may become infected if the duct becomes blocked and, when this occurs, pus accumulates within the gland. The pus may then track superiorly, inferiorly, laterally or circumferentially.

Most commonly, the pus will pass downwards in the intersphincteric plane to form a perianal abscess. It may also find its way through the external sphincter into the ischiorectal fossa and thus form an ischiorectal abscess. More rarely the pus may tract up in the intersphincteric plane and form an intersphincteric abscess or discharge down into the ischiorectal fossa through the levator ani muscles (Figure 31.24). When a perianal or ischiorectal abscess discharges through the skin, either spontaneously or as a result of surgical intervention, it may resolve completely. However, if the duct between the gland and the dentate line remains patent and becomes infected, the patient may then be left with a fistulous communication between the dentate line and the skin. According to the mode of spread the fistulous tracts can be classified in the following way (Figure 31.25):

- intersphincteric
- trans-sphincteric
- suprasphincteric
- extrasphincteric.

Intersphincteric fistulas make up about 50% of all fistulas and usually consist of a straightforward tract between the dentate line and the skin incorporating part of the internal sphincter. However, some of these can have a high intersphincteric extension and even a high opening into the rectum.

Trans-sphincteric fistulas account for about 30% and consist of a tract passing through the external sphincter. This may be low or high and occasionally may be associated with a blind high tract in the ischiorectal fossa which may even penetrate the levator ani muscles.

Suprasphincteric fistulas run above the puborectalis muscle and then descend down through the levator ani muscles into the ischiorectal fossa.

Extrasphincteric fistulas bypass the sphincter complex completely and extend from the lower rectum through the levator ani muscles and into the ischiorectal fossa.

This classification is important as it has implications for treatment.

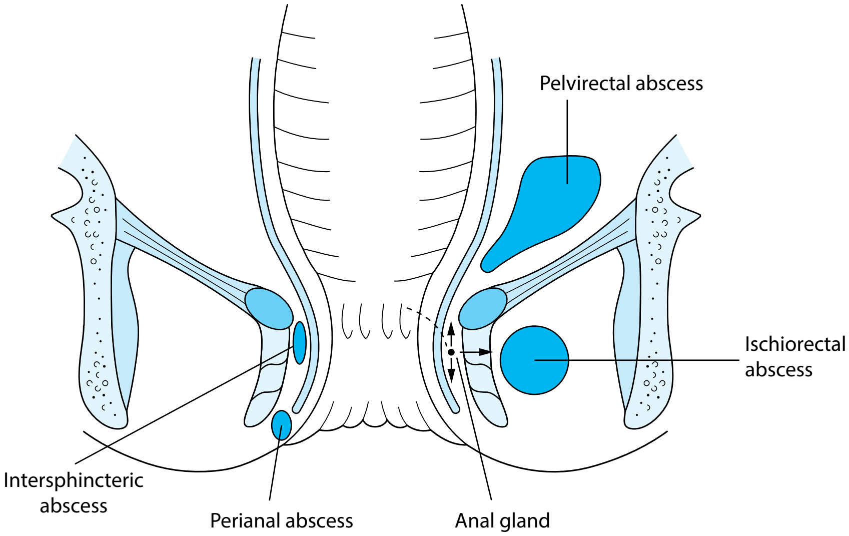

Figure 31.24 Anorectal abscesses.

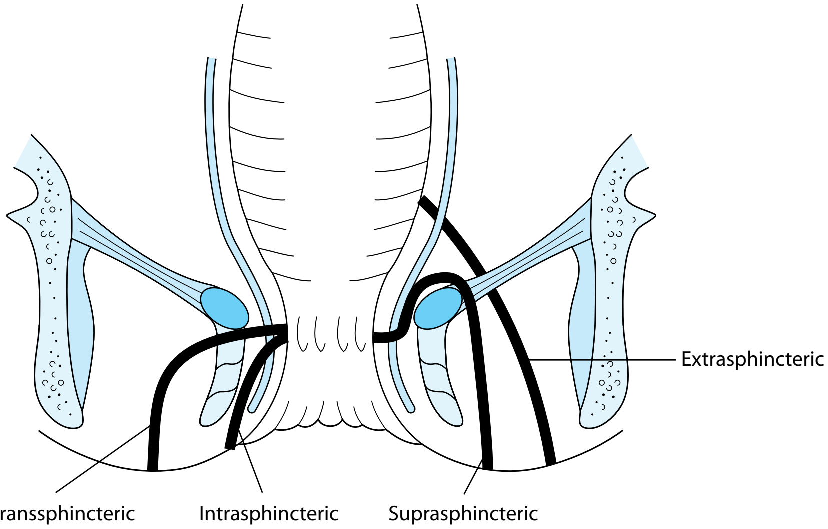

Figure 31.25 Anorectal fistulas.

Clinical features

The patient with a perianal sepsis usually presents with severe perianal pain, fever and malaise. The abscess may discharge spontaneously, but because of the severity of symptoms patients often present at hospital before this has occurred. On examination a perianal abscess is usually very obvious as a tender red swelling at the anal margin. The ischiorectal abscess, however, may be quite deep seated and more difficult to detect on clinical examination, although pressure on the ischiorectal fossa will usually give rise to severe pain. In an advanced ischiorectal abscess a large area of tender induration will be seen. Occasionally, a patient may present with an intersphincteric abscess that has not pointed at the anal canal and this can be very difficult to detect clinically. Thus, in the patient with a severe acute anal or perianal pain an examination under anaesthetic should be carried out. If there is an intersphincteric abscess this will be felt as induration through the rectal wall.

A fistula may present after discharge or incision of an abscess, usually after all the inflammation and induration has settled down in about 50% of all abscesses. Alternatively, there may be no history of abscess formation and the fistula may appear to arise *de novo*. The main symptoms are of discharge and pruritus, although occasionally a patient may notice the passage of flatus through a fistula track. There may also be a history of recurring episodes of pain relieved by discharge from the fistula.

On examination a punctate opening (or openings) can be seen, usually close to the anal verge, although sometimes a few centimetres away. Pus or serosanguinous discharge may been seen exuding from the opening particularly if digital pressure is applied over the fistula. Careful firm palpation between the opening and the anal canal will often reveal the fistulous track as a subcutaneous 'cord'. Goodsall's rule (Figure 31.26) is useful when estimating the course of a fistula; this states that, if a fistulous opening is posterior to an imaginary line drawn transversely through the middle of the anus, the track will curve round so that it opens into the dentate line in the posterior midline, whereas, if the opening is anterior, the track will be radial (i.e. it follows a straight line from the opening to the dentate line). The main exception to this rule is the anterior opening, which is ≥3 cm from the anal verge, as this may be 'horseshoeing' round from the posterior midline.

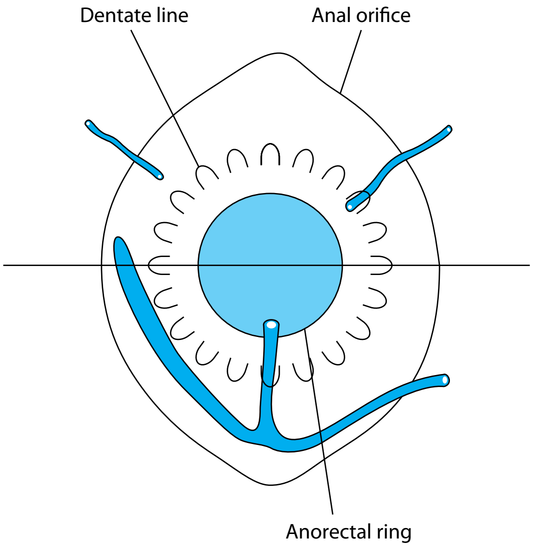

Figure 31.26 Goodsall's rule related to anal fistulas suggests that fistulas with an external opening anterior to a line drawn horizontally through the anal canal progress forwards in a radial fashion, whereas fistulas with an external opening posterior to the horizontal line curve backwards and ultimately have an internal opening in the midline posteriorly. It is possible for fistulas to extend laterally on both sides, leading to the characteristic horseshoe fistulas.

Diagnosis

The diagnosis of an abscess is usually made clinically, and its exact position relative to the sphincter complex is made at operation. Likewise, the course of a fistula is usually established by examining the patient under general anaesthesia using specially designed fistula probes. The most widely used probes are those designed by Lockhart-Mummery; these are available in a variety of configurations, and the most useful are slightly curved (Figure 31.27). The flat handle allows for precise manoeuvring of the probe, and the groove is useful for laying the fistula open (see below).

Under normal circumstances it is relatively easy to pass the probe from the external opening along the tract to the internal opening at the dentate line (Figure 31.28). In doing this it is important not to use too much force, as it is possible to create a false tract in so doing. If it proves to be impossible to find the internal opening using this technique a valuable manoeuvre is to instil a very small amount of hydrogen peroxide into the external opening by means of a fine cannula. With an Eisenhammer retractor in place within the anal canal it is then usually possible to see bubbles appearing at the site of the internal opening. This will guide further probing. In the process of probing a fistula it is important to look for extensions to the main tract. Indeed, if the probe cannot easily pass along the tract it is probably falling into a blind extension bypassing the main tract.

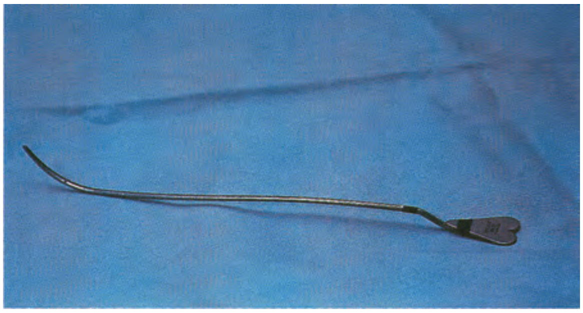

Figure 31.27 Lockhart-Mummery fistula probe.

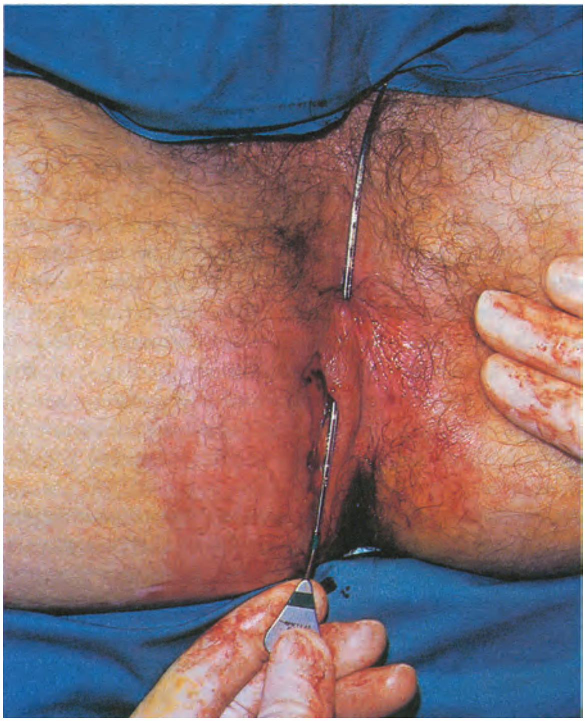

Figure 31.28 Probe in a fistula *in ano*.

Although examination under anaesthetic with probing is the most useful diagnostic approach, some forms of imaging may also be of value. Fistulography has been used in the past. However, its accuracy is sparse. Currently, fistulography has been superseded by endosonography and MRI (Figure 31.29). It appears to be particularly useful in complex fistulas with secondary extensions and abscesses and, although it is perhaps no more accurate than an examination under anaesthetic by an experienced coloproctologist, a high-quality MRI of the sphincter complex may be useful as a 'road map' to guide the surgeon. Transanal ultrasound is undertaken using a 10 mHz mechanically rotated transducer to give a 360º axial image.

Treatment

The initial treatment of a perianal or ischiorectal abscess which is pointing onto the skin is fairly straightforward. The abscess cavity should be incised and drained and an opening in the skin made that is large enough to allow continued drainage of the abscess. The cavity should not be packed tightly as this makes it uncomfortable for the patient and actually impedes drainage of the abscess cavity. A large cavity may require dressing changes in hospital until it can be managed by a community nurse. Alternatively, it is possible to put a counterincision in a large abscess and leave a drain. The patient now has to irrigate the wound in the shower twice a day but can be managed as an outpatient. The patient should always be followed up in the outpatient department to look for the development of a fistula when the cavity itself has healed. One of the complications of incision and drainage of a perianal or ischiorectal abscess is the iatrogenic production of a high fistula by overenthusiastic curetting of the abscess cavity or injudicious probing for a fistula. This must be avoided at all costs.

The best treatment for fistula *in ano* is undoubtedly a fistulotomy, laying open of the entire tract, curetting out of

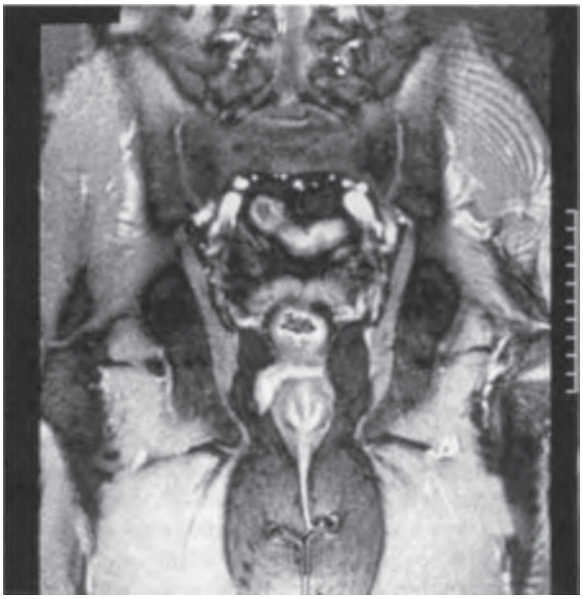

Figure 31.29 MRI scan of a fistula *in ano*. The fistula is seen as a white track curving around the anal canal. (Courtesy of Dr D. Shephard, Dundee, UK.)

the granulation tissue and leaving the wound to granulate. This is done most easily by cutting down onto the groove on the concave aspect of the fistula probe, and then using a small Volkmann's spoon to curette. Some surgeons will marsupialize the tract by suturing the divided wound edge to the edges of the fibrous tract and this is said to result in faster healing. A fistulotomy is generally safe with a simple intersphincteric fistula as the only muscle that will be divided will be the lower part of the internal sphincter. If, however, the fistula is trans-sphincteric then a fistulotomy creates a risk of incontinence. A fistulotomy of a suprasphincteric or extrasphincteric fistula will inevitably result in complete incontinence.

In the case of a low trans-sphincteric fistula that only involves a small part of the lower external sphincter, a fistulotomy is relatively safe. However, at the time of the initial examination it is important to assess exactly how much of the external sphincter is involved. It is therefore safer to establish drainage of the fistula by inserting a seton through the fistula tract. This can simply be a length of suture material or a vascular sling loosely tied. The seton controls the situation by ensuring ongoing drainage through the tract and preventing recurrent abscess formation. When the patient is awake after the procedure it is then easier to assess the anal sphincter and, if the surgeon is confident that only a small part of the external sphincter is involved, the patient can go back for laying open of the fistula.

If, however, a significant part of the external sphincter muscle is involved or if the fistula proves to be suprasphincteric, then a more conservative approach must be taken. The most widely used approach is to ensure complete drainage of all the sepsis and to leave the seton in place for several weeks. When all the sepsis and inflammation has resolved the seton can then be removed and this will result in healing in about 50% of cases. If this fails, the seton must be reinserted and a careful discussion with the patient must take place. If fistulotomy will leave some external sphincter muscle intact then this is a feasible option as long as the patient is aware that a certain degree of incontinence may result. The situation is always more difficult when some pre-existing sphincter compromise is at play and for women in general, in whom a shorter sphincter and the potential adverse effect of childbirth on the continent mechanism require to be considered.

When a seton is left in place for a longer time, it may work its way towards the surface. In this way the high fistula becomes a low fistula. The seton gradually cuts its way through the fistula tract leaving fibrosis behind it. Although the sphincter is divided more slowly than in fistulotomy the effect on continence is not very much different with some degree of incontinence in about 60% of cases.

An alternative procedure for the trans-sphincteric fistula is fistulectomy and advancement flap repair. Here the fistula tract is excised or cored out by following it up from the external orifice and dissecting through the external sphincter muscle. A flap of mucosa and internal sphincter is then raised above the internal opening and sutured down over it. This is successful in some cases, but the overall rate of success is difficult to estimate. Repeating the procedure can increase the success rate, but repeated interventions with scarring and fibrosis will in themselves impair anal canal function. A degree of laxity in the mucosa is helpful in raising a flap and may account for the lower success rates in males and in posterior versus anterior fistulas.

With a high trans-sphincteric fistula or a suprasphincteric fistula incontinence is inevitable with fistulotomy, and one approach is to give the patient a temporary colostomy, lay open the fistula and then carry out a sphincter repair after healing has taken place. Alternatively the patient may opt to live with a long-term loose seton in place. This approach is the safest in a variety of situations, including multiple fistulas and Crohn's disease.

A variety of approaches have been taken to try and induce healing of anal fistulas without resorting to fistulotomy or fistulectomy. In general, the aim has been to fill the tract with biological material in the hope that it will be slowly replaced by the body's own tissue, leaving a healed fistula tract. Injection of fibrin glue was used quite extensively. Initial results seemed promising but long-term results have been poor with high recurrence rates. The liquid consistency of fibrin glue is possibly not ideal for the purpose of closing anorectal fistulas, because the glue is easily extruded from the fistula tract by increased intraluminal pressure. A plug fabricated from porcine collagen, which is claimed to stimulate tissue remodelling leading to closure of the fistulous tract, is currently being used. The tract is cleaned out, the plug is pulled into position and then sutured in place with the mucosa closed over the top (Figure 31.30). A multicentre randomized controlled trial is now taking place in the UK comparing this plug with a cutting seton approach (Fistula In Ano Trial – FIAT).

The extrasphincteric complex fistula, which is usually secondary to Crohn's disease or trauma, is particularly difficult to deal with and, particularly in Crohn's disease, it may be better to avoid surgical interference. In such patients, a long-term seton may be the answer and some patients may require a defunctioning colostomy. After resolution of the sepsis, laying open of the fistula and subsequent sphincter repair may be possible, but the ultimate results can be less than ideal.

Current interest surrounds the LIFT (ligation of intersphincteric fistula tract) procedure. This involves dissection upwards in the intersphincteric space to the level of the fistula which is then ligated and divided. The external fistula is curetted. The technique is attractive as it has minimal impact

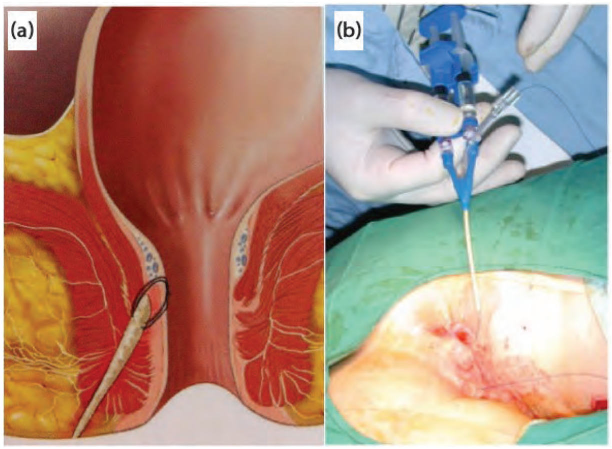

Figure 31.30 Fistula plug (a) and fibrin glue (b).

on the sphincter muscle. A variation is to insert a small sheet of biomaterial between the divided ends of sphincter (BioLIFT). Early results are encouraging but wider experience and long-term follow-up are required to fully assess its role.

Pilonidal sinus and abscess

Pilonidal sinus is a condition that occurs mostly in the natal cleft of young males. It is characterized by multiple subcutaneous sinuses and abscess cavities containing hair.

Aetiology and pathology

There is very little evidence for a congenital origin in this condition and current consensus favours an acquired mechanism. It is thought that frictional forces generated in the depths of the natal cleft tend to drive hairs subcutaneously, where they generate a foreign body reaction. Secondary infection may compound the problem, leading to abscess formation.

Clinical features

Pilonidal sinus may be asymptomatic and only present on routine inspection. However, if the sinuses become infected the patient may have pain and discharge in the natal cleft. On examination there are a variable number of pits seen in the upper natal cleft (Figure 31.31) and, in active inflammatory disease, these may be seen to be exuding pus. When an abscess forms there will be a red tender swelling just to one side of the natal cleft. Although the appearances are typical, occasionally a pilonidal sinus may be mistaken for a fistula *in ano* and vice versa. The diagnosis is made on clinical grounds and specific investigations are not generally required. Sometimes a granuloma can be seen on excised specimens.

Treatment

If asymptomatic pits are found then no treatment is required. If a patient presents with a pilonidal abscess then this should be incised and drained, and the patient kept under review until the wound has healed. Thereafter, a decision can be made regarding excision. The most difficult situation to treat is the patient with chronic discharging sinuses, and this requires a fairly radical surgical approach.

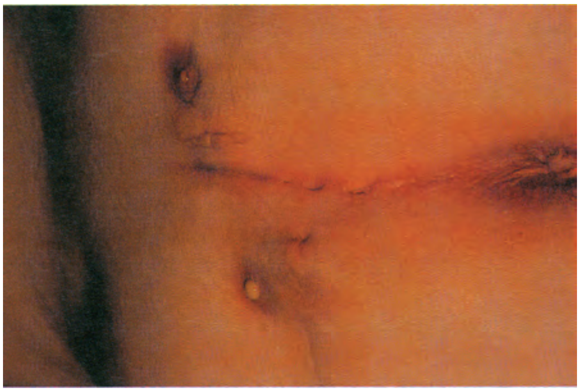

Figure 31.31 Pilonidal sinus. Midline pits in the natal cleft with distant fistulous openings. (Courtesy of Mr R.A.B. Wood, Dundee, UK.)

The traditional approach has been excision of the sinus-bearing area down to the deep fascia and removal of all sinuses and nests of hair. Surgical opinion is then divided as to whether this should be left open to granulate or whether primary closure should be attempted. If the latter approach is employed almost 50% of the wounds will break down and healing by secondary intention will be necessary. In a patient who has pits that are some distance from the main disease in the natal cleft an elliptical excision of the main area may be carried out in association with 'coring out' of the long extensions. These need to be left open to heal by secondary intention. The long-term recurrence rate after excision of pilonidal sinus is in the region of 20%.

Many attempts have been made to design a definitive procedure for this condition. The plethora of approaches reflects the lack of a single procedure combining a proportionate level of complexity with reproducible efficacy.

Interest has focused on relocating the suture line away from the midline and obliterating the midline cleft. Procedures such as those described by Bascom, Karydakis and Limberg share this aim using a variety of approaches. These techniques do have better results, but can be extensive.

Hidradenitis suppurativa

Apocrine glands are found in certain zones including the axillae, the inguinoscrotal and perianal regions and the breasts. These glands develop from hair follicles and discharge a thick secretion into the follicle or onto the adjacent skin. As they are not active until puberty, inflammation of these glands (hidradenitis) does not usually appear until the third decade. Clinically, the affected area becomes indurated then forms sinuses with the discharge of small amounts of pus. Although the axillae are the most predominantly affected areas the perianal region is involved in about 30%.

Conservative treatment is the first approach. The patients are advised to wear cotton underwear and avoid shaving with razorblades. Betadine scrubs can be helpful. During active periods the hidradenitis may require treatment with antibiotics. Sometimes long-term rotating courses are required. When severe, treatment requires excision of the affected skin and subcutaneous tissue down to the deep fascia, and, when extensive, split skin grafting is necessary to provide cover. If the perianal region is extensively affected it may be necessary to carry out a temporary defunctioning colostomy to allow excision and skin grafting. There is a strong tendency to recurrence of the disease.

The development of squamous cell carcinoma has been described in patients with long-standing perianal hidradenitis suppurativa.

Perianal Crohn's disease

Anywhere between 30% and 70% of patients with Crohn's disease may have some involvement of the anal canal. This is more common in patients with colonic and particularly rectal Crohn's disease, but it may occur in isolation or in association with Crohn's disease elsewhere in the gastrointestinal tract.

BOX 31.2 Classification of Crohn perianal lesions (after Hughes)

- Primary lesions
  - Anal fissure
  - Oedematous piles
  - Ulceration
- Secondary lesions
  - Skin tags
  - Anal stricture
  - Perianal abscess and fistula
  - Anovaginal and rectovaginal fistula
  - Carcinoma
- Incidental lesions
  - Piles
  - Skin tags
  - Perianal sepsis
  - Hidradenitis suppurativa

The perianal lesions are variable and have been classified by Hughes (Box 31.2); according to this classification the primary lesions consist of anal fissure, ulcerated oedematous haemorrhoids and deep ulceration of the anal canal or lower rectum. These can lead to the secondary lesions of oedematous skin tags, anal or rectal stricturing, perianal abscess and fistula formation, and rectovaginal or anovaginal fistula. It must also be remembered that Crohn's disease is potentially a premalignant condition and carcinoma of the rectum or anal canal may complicate this disease.

The severity of perianal Crohn's disease is highly variable and may cause only minor irritation. On the other hand, in a patient with multiple fistulas ('watering can' anus) the severity of the symptoms may necessitate proctectomy. The management of perianal Crohn's disease is conservative where at all possible. The disease is characterized by poor healing following surgical intervention. Metronidazole is particularly useful but can require prolonged courses, which risk the onset of neuropathy. Ciprofloxacin is also associated with good results, but use recently has been tempered by the incidence of *Clostridium difficile* infection.

Surgical intervention is required for eradication of sepsis and this involves draining abscesses and inserting setons into fistulas. Frequently, the fistulas are high and may be extrasphincteric so that laying open of a Crohn's fistula is usually contraindicated. Occasionally, with severe disease, proctectomy is necessary, but this should only be carried out after sepsis has been controlled; otherwise, an infected perineal sinus is likely to result.

New biological therapies and advances in MRI mean that the assessment and management of perianal Crohn's disease should now require a multidisciplinary approach involving a surgeon gastroenterologist and radiologist. There have been some encouraging results in the treatment of Crohn's anal fistulas with antitumour necrosis factor (anti-TNF) antibody therapy, but it is likely that sustained therapy is necessary to maintain improvement. In addition, caution is required as increased abscess rates have been observed and radiological assessments demonstrate persisting fistula appearances even when clinical healing has been achieved. An examination under anaesthesia is usually required to eradicate any obvious ongoing sepsis prior to commencing anti-TNF therapy. The exact management of a seton suture during therapy remains to be established. Early removal will risk abscess formation whereas delayed removal may prevent healing. Further studies on the length of therapy, dosing interval, second antibody and other factors are required to establish what the place of these therapies in long-term healing of Crohn's anal fistulas might be.

Anovaginal fistulas are particularly distressing and will usually require intervention. Good control of Crohn's disease combined with advancement flap repair gives the best chance of success but recurrence is common. Bringing in healthy tissue for interposition such as gracilis muscle may be necessary.

Anal fissure

An anal fissure is a linear ulcer that occurs in the anal canal just distal to the dentate line. This may be caused by Crohn's disease or trauma but most commonly it is a primary condition. It affects both men and women and the highest incidence is in the third and fourth decades of life. It may occur soon after pregnancy and vaginal delivery.

Aetiology and pathology

The initiating factors in anal fissure are unclear, although minor anal trauma caused by passage of a constipated stool has been suggested. The main underlying pathology, however, appears to be a high resting anal pressure caused by increased internal sphincter tone. The blood supply to the anal canal has to pass through the internal sphincter and therefore spasm of this muscle reduces the blood flow and the oxygen tension in the skin of the anal canal. Interestingly, the fissures tend to occur at the watershed of the blood supply, i.e. the anterior and posterior midline in women and the posterior midline in men.

Clinical features

The typical clinical features are of pain on defecation associated with bright red bleeding. This may be associated with pruritus ani and discharge of mucus. On examination there is usually a skin tag overlying the fissure and the fissure itself can be seen by everting the anal canal using lateral traction (Figure 31.32). This will reveal a sharply defined ulcer and it may be possible to see the lower fibres of the internal sphincter at its base. Digital rectal examination or proctoscopy should not be attempted in the conscious patient as this will cause considerable discomfort.

Diagnosis

In terms of making a diagnosis this is done clinically, but it is important to exclude other conditions such as Crohn's disease or malignancy. This can be established by examination under anaesthesia and biopsy when appropriate.

Treatment

The underlying principle of treating anal fissures is to reduce the internal anal sphincter tone. In patients with minimal

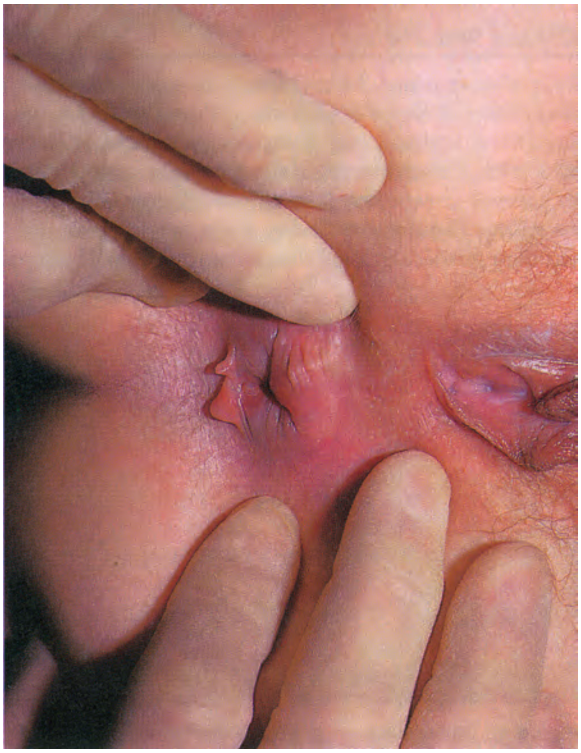

Figure 31.32 Anal fissure.

symptoms this may be achieved by topical application of a local anaesthetic and bulk laxatives. In patients with more severe symptoms, however, the use of 0.2% GT) cream applied two or three times a day can produce healing of fissures in about 50% of cases. Topical diltiazem has a similar effect but may be better tolerated. These agents probably act by both relaxing internal anal sphincter and improving the blood flow owing to their vasoactive properties. The healing takes about 6–12 weeks. For the patient unable or unwilling to use topical application oral nifedipine can have a similar effect.

If these approaches fail then a trial of temporary paralysis of the internal anal sphincter by botulinum toxin type A injection is worth trying and has the advantage that the effects will wear off without leaving any permanent sphincter compromise. The dosage and site of injection (intersphincteric versus intramuscular) is debated as is the exact mode of action of botulinum toxin in this situation. Few adverse effects have been reported and this approach may reasonably be positioned between topical treatments and surgical intervention. If this does not work the first time, it can be repeated after 6 weeks.

If medical treatment and botulinum toxin injection fail then a surgical approach becomes necessary. Historically, forced anal dilatation (Lord procedure) was performed and, although effective, this was associated with an unacceptable level of incontinence. The surgical treatment of choice is now a lateral sphincterotomy, which involves dividing the internal sphincter at one point on the lateral wall of the anal canal up to the level of the dentate line. This is achieved by inserting an anal retractor so that the internal sphincter is gently stretched and easily palpable. A small incision is then made on the lateral aspect of the anal canal just below the internal sphincter. Using scissors the intersphincteric plane is developed, as is the plane between the anal skin and the internal sphincter. The scissors are then used to divide the sphincter and bleeding is controlled by firm finger pressure. Lateral sphincterotomy is said to be successful in about 95% of cases, but patients should be warned that it can be associated with minor degrees of incontinence to flatus or mucus. Adjustments to the surgical technique to diminish the incidence of incontinence include never extending the sphincter incision above the top of the fissure or beyond the dentate line.

An alternative approach is required in refractory cases and when there is pre-existing sphincter compromise. These are frequently cases in which sphincter pressure is low as opposed to the ultra-high pressures usually noted in anal fissure. These cases merit full investigation by anorectal physiology and anal ultrasound. Ultrasound may reveal a fully intact internal anal sphincter in cases of failed lateral sphincterotomy and suggest that the procedure was inadequate and may be repeated. Otherwise, a mucosal advancement flap can be used with a fissurectomy or the 'house' advancement flap, which aims to cover the exposed internal anal sphincter fibres by advancing skin from the anal verge upwards to cover the excised fissure bed.

Pruritus ani

Pruritus ani or perianal itching is a common condition. There are a large number of anorectal and dermatological conditions that may give rise to this symptom, but in the vast majority it is idiopathic. The primary cause is probably minor anal leakage as the result of internal sphincter dysfunction. This sets up an irritation that is exacerbated by brisk cleansing or scratching. This may then introduce fungal infection that intensifies the pruritus. Another important cause is use of wet, perfumed toilet paper, giving rise to chemical irritation or allergic reaction.

When taking a history it is particularly important to establish whether the family includes small children as this would predispose to *Enterobius* infestation (threadworm). On examination the perineal skin should be closely inspected to look for signs of dermatological disease. In idiopathic pruritus there is typically perianal excoriation and ichthyosis. Digital examination of the rectum should be carried out in order to assess the anal tone and proctoscopy to look for the presence of haemorrhoids. Perianal lesions or areas of abnormal skin should be biopsied and, when appropriate, skin scrapings should be examined for fungal infestation.

If *Enterobius* infestation is suspected, the Sellotape test should be carried out. This involves placing adhesive tape over the anus and then transferring it to a glass microscope slide. Histological examination will subsequently reveal the presence of ova that have been deposited on the perianal skin.

The treatment of pruritus ani depends on any underlying cause. Prolapsing haemorrhoids, anal polyps and skin tags should be treated surgically. *Enterobius* infestation can be treated using mebendazole. If there is a primary skin condition the patient should be referred to a dermatologist. In the case of idiopathic pruritus advice should be given in order to minimize anal leakage and damage to the perianal skin. This involves dietary modification to reduce excessive flatulence or loose stool. The patient should also be advised to keep as clean and dry as possible and to avoid scratching. In case of some leakage, rectoanal irrigation can be performed by a small irrigation bottle. When the pruritus is intense and particularly if a fungal infection is suspected then a cream containing steroid and an antifungal agent (e.g. clotrimazole) can be used in the short term to break the cycle of itching and scratching.

In extreme cases of pruritus ani, ablation of the sensory nerves by subdermal injection of methylene blue has been used.

Perianal warts

Perianal warts or anal condylomata are caused by infection with human papillomavirus (HPV) and is a sexually transmitted disease. It is found in between 40% and 70% of males who have sex with males. Subtypes of the virus that are implicated in the development of these lesions are 6, 11, 16 and 18. The most common is subtype 6, but subtypes 16 and 18 are important in that they are associated with a high incidence of dysplasia and malignant transformation. In women, about 80% will have associated warts on the external genitalia, vagina or cervix and about 20% of men will have warts on the penis.

Clinically, patients tend to present with perianal itching and bleeding, and on examination warts are seen in the perianal region with varying degrees of confluence (Figure 31.33). In patients with AIDS, the warts tend to form a dense confluent sheet.

There are various methods of treatment, and, for relatively mild disease with isolated warts, 25% podophyllin in either liquid paraffin or tincture of benzoin can be applied. Intervening normal skin should be avoided as podophyllin is very irritant and may give rise to skin necrosis. In general, although podophyllin treatment is effective the results are not as good as surgical excision, which is the preferred method.

Excision involves operating on the patient in the prone jack-knife or lithotomy position and a 1:200 000 solution of epinephrine (adrenaline) is injected subcutaneously. By causing swelling in the perianal skin, this separates the warts and they can be excised individually with scissors. The rate of recurrence after complete excision of all perianal warts is in the region of 10%. Unfortunately, this approach can be difficult when the warts are extremely confluent and it may be necessary to resort to electrocoagulation or cryotherapy. Both of these result in quite severe tissue damage and anal stenosis is a possible complication. Recently, an autologous vaccine prepared from the patient's own warts has been described and this appears to be highly effective not only in eradicating the warts but also in reducing the rate of recurrence. Interferon has also been used to good effect.

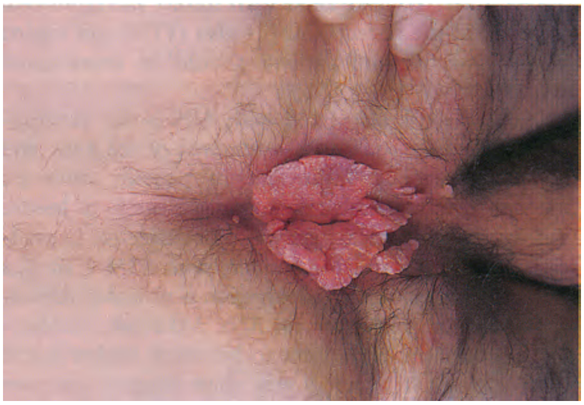

Figure 31.33 Perianal warts.

Anal intraepithelial neoplasia

As is the case with perianal warts, anal intraepithelial neoplasia (AIN) is caused by HPV and appears to be sexually transmitted. HPV types 6, 11, 16, 18, 31 and 33 can all be implicated. On histological examination epithelial dysplasia is seen and this is graded as 1–3 according to the epithelial depth of dysplasia. Thus, in grade 1 only the upper third is affected; in grade 2 the upper two-thirds; and in grade 3 the whole thickness of the epithelium is dysplastic. Grade 3 AIN is also classified as carcinoma *in situ*.

Clinically, patients present with perianal discomfort, itching and bleeding and on examination the perianal epithelium is thickened and may have a whitish appearance. This may be exaggerated by the application of acetic acid, which is useful in targeting areas for biopsy. High-resolution anoscopy is a new promising instrument to detect lesions early.

In women, it is important to appreciate that AIN may be associated with similar intraepithelial neoplasia of the cervix, vulva and vagina and affected patients should be investigated appropriately.

The main risk associated with AIN is the development of invasive squamous carcinoma of the anus, and the treatment and follow-up of patients must be directed towards early detection of such a lesion. Unfortunately, surgical excision is not effective in eradicating the virus and for patients with AIN 1 or 2, a simple policy of regular observation is probably regarded as adequate. However, for AIN 3 the risk of developing carcinoma is thought to be much higher and if there is a small affected area then surgical excision would seem to be appropriate. However, when there is a large circumferential area of AIN 3, treatment is much more difficult. Some have recommended complete excision of the affected area with split skin grafting. However, this requires the formation of defunctioning colostomy and is associated with a high risk of anal stenosis. In addition, it does not effectively eradicate the virus. Imiquimod, which acts as an immune response modifier, is reported to have a good effect on AIN, but further studies need to be conducted. Currently, therefore, it is recommended that such patients be followed up 6 monthly with careful inspection and biopsy with intervention only if invasive malignancy develops.

These patients should be treated by a multidisciplinary team, including a gynaecologist and a dermatologist.

Anal cancer

Anal cancer accounts for only about 5% of all carcinomas of the large bowel and it is nearly always a squamous carcinoma. Rarely, adenocarcinoma may be seen but this is usually a very low rectal cancer involving the anal canal. Carcinomas near the dentate line are mostly mixed squamous cell carcinomas and adenocarcinomas (adenosquamous carcinomas). Another very rare condition is malignant melanoma of the anal canal. This section will, however, deal exclusively with squamous carcinoma. Histologically anal cancer is termed epidermoid and this may be subclassified as squamous cell, basaloid (or cloacogenic) or mucoepidermoid. This classification does not appear to have any prognostic significance, because there is no difference between the squamous cell carcinoma and the adenosquamous carcinoma in regard to treatment, response to treatment and prognosis. Local spread of an anal cancer tends to occur proximally and radially into the rectum and anal sphincters. In advanced cases it may also involve the vagina. Lymphatic spread is to the perirectal and inguinal lymph nodes. Distant metastases occur most frequently in liver, lung and bones but this is usually associated with advanced local disease.

Aetiology

It is now clear that the majority of anal cancers are associated with HPV infection, although not all patients will have a clear-cut history of perianal warts or AIN. The relationship seems clearer for cancers from within the canal as opposed to from the perianal skin. The carcinogenic factors involved are not clear, but immunosuppression or HIV infection appear to increase the incidence of anal cancer.

Clinical features

Patients tend to present with anal pain and bleeding and some will notice a mass in the anal canal. On examination the typical appearance is of a malignant ulcer at the anal margin or within the anal canal. It is also important to examine the inguinal region, although when inguinal lymph nodes are enlarged only about 50% will have metastatic spread on histological examination. Delay in presentation occurs when symptoms are attributed to haemorrhoids. Atypical features and disproportionate pain should always arouse suspicion.

Investigation

Clearly the most important investigation is biopsy of the anal lesion, but examination under anaesthetic is extremely important in evaluating the extent of disease and its resectability with primary surgery. MRI of the pelvis with gadolinium and endorectal ultrasound are useful in assessment of the primary cancer. A CT scan of the chest, abdomen and pelvis is required for full staging of the disease.

Classification

The treatment of anal carcinoma is based on the location of the tumour and the tumour (T)–node (N)–metastasis (M) classification.

Location

A squamous cell carcinoma of the skin more than 2 cm from the dentate line, without involvement of anal canal, needs to be treated as a squamous carcinoma of the perineal skin. A squamous cell carcinoma of the skin within 2 cm of the dentate line with involvement of anal canal needs to be treated as a squamous carcinoma of the anal canal.

Treatment

This is as follows:

- Perianal skin
  - Tis: local excision; if margins are not clear then adjuvant radiotherapy.
  - T1N0M0: local excision with a 1 cm margin; when the margin is too small, there should be adjuvant radiotherapy to the primary tumour field.
  - T2 (≤4 cm) N0M0: radiotherapy to the primary tumour and inguinal lymph nodes.
  - T2 (>4 cm) to T4N0M0: chemoradiotherapy for the primary tumour and inguinal lymph nodes.
  - T2–4N1–3M0: chemoradiotherapy to the primary tumour and lymph nodes.
  - T1–4N0–3M1: individualized approach.
- Anal canal
  - Tis: local excision; when margins are not clear use adjuvant radiotherapy.
  - T1–2 (≤4 cm) N0M0: radiotherapy to the primary tumour.
  - T2 (> 4 cm) to T4N0M0: chemoradiotherapy for the primary tumour and pelvic and inguinal lymph nodes.
  - T1–4N1–3M0: chemoradiotherapy to the primary tumour and lymph nodes.
  - T1–4N0–3M1: individualized approach.

Surgery retains an important role in the treatment of anal cancer. About 35% of patients undergoing combined radiochemotherapy will either experience recurrence or fail to fully respond to the treatment. In this case, radical surgery in the form of abdominoperineal excision of the rectum is necessary. In addition, some patients may have such a debilitating tumour that defunctioning colostomy is necessary while they are having the radiochemotherapy. Although chemoradiation is effective and may avoid a stoma, patients require full information on the long-term effects, especially in relation to bladder and sexual function. Younger patients may opt for a primary surgical approach. When there is residual tumour after primary surgical resection chemoradiotherapy is indicated.

Follow-up

A programme of regular follow-up is required to optimize early detection of residual tumour after primary treatment, local recurrence and inguinal lymph node metastases. Targets of later follow-up include treatment side effects such as radionecrosis and secondary tumours after chemoradiotherapy.

Surgery

Significant changes in surgical training have occurred over the past decade, with the inevitable progress towards specialization in the various surgical specialties. The current edition of *Essential Surgical Practice: Higher Surgical Training in General Surgery* reflects these latest developments with a new structure that accurately mirrors current surgical training. This new edition excludes surgical specialties that are distinct from general surgery, allowing an increased focus on topics of direct relevance to trainees in higher surgical training.

Over 31 chapters, the book provides detailed information on those specialties of which the general surgeon is required to have a working knowledge, and highlights core information for revision and quick reference. Topics include:

- Surgical biology and pathology
- Surgical craft approaches and technologies
- Perioperative care
- Cardiovascular, pulmonary and renal pathophysiology
- Surgical infections
- Interventional radiology
- Trauma and head injuries
- Disorders of the thyroid and adrenal glands
- Disorders of the stomach, liver, spleen, colon and pancreas
- Bariatric surgery

This book can be used with confidence by those enrolled in local courses and is also consistent with the scope and level of information required for international postgraduate examinations, such as the Joint Surgical Colleges' Fellowship Examination. To enhance the book's utility, the print edition includes complimentary access to a VitalSource ebook online and offline on your PC or Mac, iPhone®/iPod Touch®/iPad®, Kindle Fire or Android™ device.
